Glossary

Autogenic species A species that creates habitat for other organisms; this habitat would not exist if the autogenic species was absent.

Chemoautotrophic Primary production of organic matter using energy derived from chemical reactions rather than from photons.

Dyke intrusion Upwelling magma; may reach the surface of the crust to flow out as lava and solidify as basalt.

End-member fluid In black smokers, the hot, chemically modified fluid that develops at depth in the crust and exits undiluted by seawater.

Euphotic zone Sunlit upper layer of the ocean that can support photosynthesis.

Heterotrophy Organism that relies on organic material (other organisms, pieces of organisms, dissolved organic material) for its nutrition.

Hydrothermal plumes Created by rising black smoker effluents that mix turbulently with the surrounding seawater, becoming dilute and eventually reaching neutral buoyancy (typically ~200 m above the black smoker source); once neutral, they spread laterally and are detectable by chemical and physical tracers for kilometers.

Mid-ocean ridge Crustal accretion boundaries between major tectonic plates that make up the ocean crust.

Phylotypes Molecularly differentiated taxa.

Plume prospecting Use of chemical and physical anomalies in hydrothermal plumes to locate hydrothermal vents.

Spreading rate The rate at which tectonic plates move apart from each other.

Symbiont One of a pair of coexisting, mutually supportive organisms; in vent invertebrate-bacteria symbioses, the “symbiont” colloquially refers to the bacterium associated with the host invertebrate tissue; endosymbiont—within the host invertebrate (intra- or extracellularly); episymbiont—on the outer surface of the host invertebrate.

Tectonism Forces that disturb and dislocate the Earth’s crust (earthquakes).

Vicariant event A historical event that isolates species’ populations and leads to speciation (e.g., the closing of the Isthmus of Panama); usually considered in a geological context, but human activities also generate vicariant events.

Midocean Ridges and the Hydrothermal Setting

Although deep-sea hydrothermal vents occur in a variety of geological settings, including isolated back-arc spreading centers (such as the one that lies behind the Mariana Trench) and seamounts (e.g., Loihi, the incipient Hawaiian island), most hydrothermal systems lie along the network of volcanic midocean ridges that girdle the globe. Midocean ridges are the boundaries between the tectonic plates that make up the ocean crust; as such, they are the locus of episodic volcanism and earthquake activity associated with magmatic dyke intrusions and seafloor spreading. Most of the midocean ridge (and thus its hydrothermal systems) lies well below the euphotic zone, at depths greater than 2000 m. Where ridges intersect continents (e.g., at the head of the Gulf of California) or shoal to volcanic islands (e.g., Iceland and the Azores), hydrothermal systems may be found at shallower depths and even intertidally.

The geological pavement of deep-sea vents is typically hard basalt. Local relief of the basalt varies from flat, featureless sheets to smooth lobate surfaces a few to tens of centimeters high to rounded pillows of a meter or more relief. There are a small number of locales where sedimentation rate is in excess of volcanism, resulting in soft-sedimented bottoms with intruding basalt sills. The two best known sediment-hosted

hydrothermal systems are in Guaymas Basin (Gulf of Mexico), where terrestrial runoff and pelagic production rates are high, and portions of the Gorda Ridge (off Oregon) and the northern Juan de Fuca Ridge (off Vancouver, Canada), where terrigenous inputs from the continental margin are significant.

Hot springs develop on midocean ridges where sea-water can penetrate ~2 km into the porous basalt crust to reach hot rock. In this “reaction zone” at depth, seawater reacts with the basalt, losing all of its magnesium and oxygen and becoming enriched in metals and reduced compounds, including hydrogen sulfide. The resulting acidic, hot water is thermally buoyant and rises to the seafloor to exit as high-temperature (typically 350 °C) fluids. As the vent fluid exits, it mixes with the cold, nearly neutral seawater and precipitates mineral sulfides of copper, iron, and zinc, forming substantial mineral chimneys known as black smokers. Where venting is persistent over time, chimneys coalesce to form larger, hydrodynamically and topographically complex sulfide edifices tens to hundreds of meters in diameter. Plumes emitted from black smokers rise ~200 m, until they become neutrally buoyant and spread out laterally. Hundredths of a degree deviations from ambient temperatures, elevated particulate concentrations, and modified chemistry allow water column geochemists to undertake “plume prospecting” by towing sensor packages at the depth of the neutrally buoyant plume. This prospecting method

permits extensive mapping of ridge segments to yield integrated measures of hydrothermal output. Plume prospecting is also critical in locating new hydrothermal fields in unexplored ocean basins.

Not all of the vent fluid escapes as high-temperature fluid. Large volumes of warm, sulfide-laden water are emitted as “diffuse flow” vents where ambient seawater has mixed with the end-member fluid. It is this warm-water flow that sustains productive populations of free-living chemoautotrophic, thermophilic microorganisms (up to 115 °C) and dense invertebrate populations (typically <40 °C). These diffuse flows may issue from porous surfaces of sulfide-mineral structures or directly from cracks and fissures in basalt lavas and can contribute an order of magnitude more flow than the focused output of black smokers at some sites. Because there are large gradients in chemistry and temperature within vent ecosystems, there is a large potential for diverse microbial and invertebrate types.

Hydrothermal vent fields, typically consisting of multiple discrete zones of focused and diffuse flows, are the basic unit of hydrothermal activity on a ridge axis. Vent fields vary in size from hundreds to thousands of square meters and represent islands of productive habitat within an otherwise relatively barren, hard-substrate environment.

The tectonic plates that make up the crust do not all move apart at the same rate. Spreading rate is a function of magma supply, with fastest spreading centers (100–170 mm year⁻¹) associated with well-developed magma chambers and supporting a higher spatial frequency of hydrothermal systems than slow-spreading systems (moving apart at 10–50 mm year⁻¹). As will be seen below, spreading rate may have a profound influence on diversity and biogeography of vent invertebrate communities because of its control on the spacing between vents. Other features vary with spreading rate, including the relative longevity of venting sites and bathymetric isolation of near-bottom waters. The two end members of the spreading rate continuum include the slow-spreading Mid-Atlantic Ridge, characterized by long-lived (thousands of years) vent systems and deep, basinlike valleys within which vents are located, and the fast-spreading East Pacific Rise, where vents are relatively short-lived (months to years to decades) and occur on topographic highs.

Microbial Diversity

Free-Living Microorganisms

Deep-sea hydrothermal vent ecosystems are celebrated as sites where chemosynthesis by microorganisms sustains primary production and a huge biomass of primary and secondary invertebrate consumers. The generation of biomass in the system is driven primarily by the microbial oxidation of sulfide, which yields biochemical energy for the fixation of CO₂. Inasmuch as the oxygen used in sulfide oxidation comes from seawater and ultimately from photosynthesis, the larger part of the vent ecosystem cannot be said to be totally independent of sunlight.

The potential metabolic diversity of vent microorganisms is large, with both aerobic and anaerobic poises. Reduced sulfur

substrates, iron, manganese, ammonia, methane, and hydrogen can all serve as electron donors, leading to sulfide, sulfur, and thiosulfate oxidation, iron and manganese oxidation, nitrification, methane and hydrogen oxidation, denitrification, sulfur and sulfate reduction, and methanogenesis. While microbial isolates may be induced to be strictly autotrophic in the laboratory, mixotrophy may be the rule in the natural environment, with assimilation of simple organic compounds (heterotrophy) whenever they are available. Physiological diversity of microorganisms may also be great, with microbial types optimized for life in extreme temperatures (perhaps to >115 °C; superthermophiles), high temperatures (50–115 °C; hyperthermophiles and thermophiles), intermediate temperatures (10–50 °C; mesophiles), and cold temperatures (<10 °C; psychrophiles). Microorganisms can be pressure tolerant or barophilic (unable to survive low pressure). Microbial habitats include low-temperature diffuse-flow environments, buoyant plumes, interstices of sulfide structures, and surfaces of rocks and organisms. There is also growing evidence for an expansive, deep subsurface biosphere within the porous upper layer of the ocean crust, wherever temperatures are compatible with life.

Diversity of microbial communities at the level of species or phylotype is one of the outstanding issues in microbial ecology. Isolates cultured from deep-sea samples may only deliver a few percent of the actual diversity within the system. Current research combines traditional culture methods with molecular characterization of natural communities. Within vent systems, microbial communities may be dominated by a single phylotype, as in the case of bacteria associated with mineral sulfides at black smoker chimneys on the Mid-Atlantic Ridge. Dominance by a small number of phylotypes is also observed at the Loihi Seamount hydrothermal vents. The dominance of microbial communities by a small number of taxa is reminiscent of species-abundance characteristics observed in studies of diversity in marine invertebrate communities from “extreme” environments. It is, however, too soon to conclude that there is any single pattern of microbial diversity in the free-living microbial populations at hydrothermal vents. An even greater unknown is the degree to which vent microorganisms express biogeographic patterns. The current dogma is that free-living bacteria have unlimited dispersal capabilities in the open ocean because they can drift indefinitely in an inactive state. Hydrothermal vents may prove to be an ideal system in which to test this hypothesis with rigor at a global scale.

Biotechnology industries have embraced the vent ecosystem as a source of novel microbial organisms and enzymes that operate under extreme conditions. The prospect of thermostable or barophilic enzymes in particular has led to systematic assays of deep-sea microbial communities for industrial applications. Where microorganisms live at meso- and thermophilic temperatures in organic-rich sediments, they are implicated in transformation and decomposition of freshly cracked organic material. Microbial hydrocarbon processors are obvious targets for extraction and design of enzyme systems by petroleum and environmental waste management industries. Microorganisms from vents are also screened for exceptional therapeutic properties. Biotechnology interests thus place an added emphasis on discovery and isolation of as many microorganisms as possible from vent ecosystems.

Bacterial–Invertebrate Symbioses

Deep-sea hydrothermal vents are distinguished from their shallow-water and terrestrial hot-spring counterparts by the hugely successful associations between chemoautotrophic, endosymbiotic microorganisms and their macroinvertebrate hosts. Endosymbiotic bacteria are now known from a number of deep-sea invertebrate groups, including the bivalve and gastropod mollusks, vestimentiferan and pogonophoran annelids, and sponges. It is the vestimentiferan tubeworms that exhibit the greatest anatomical and physiological accommodation of the symbionts. As adults, tubeworms lack a mouth and gut, having instead a special organ—the trophosome—derived from gut tissues and made up of host cells filled with bacteria, all bathed in hemoglobin-rich fluids. Symbiont acquisition in tubeworms is by ingestion from the environment when the worm is in its larval and/or postlarval stage and still has a digestive system. Is there more than one tubeworm symbiont species in the environment? Based on DNA–DNA hybridization techniques, the sulfide-oxidizing chemoautotrophic endosymbionts of two co-occurring species of vestimentiferans belonging to different genera (*Riftia pachyptila* and *Tevnia jerichonana*) were found to be identical. Geographically distant populations of *R. pachyptila* have been shown to host this same symbiont, although DNA fingerprinting can discriminate symbionts among populations. A geographically disjunct population of the vestimentiferan worm, *Ridgeia piscesae*, from within the same ocean basin also hosted this same symbiont. A second symbiont was discovered in the vestimentiferan *Lamellibrachia* sp., but, because this species occurs in the Gulf of Mexico, this may be a basin-scale difference in the distribution of infective symbiont species.

Vesicomyid clams found at hydrothermal vents also host chemoautotrophic bacteria and have nonfunctional guts. In contrast to the vestimentiferan tubeworms, symbionts are transmitted maternally in the clams and there is, accordingly, strict fidelity between a symbiont species and its host species. A map of phylogenetic relationships among species of vesicomyid clams is remarkably congruent with the phylogenetic map of their respective symbiont species, and is evidence of cospeciation of host and symbiont.

There is physiological diversity in microbial endosymbionts of vent taxa. Sulfide oxidizers predominate in vestimentiferan tubeworms, but there is at least one instance of a tubeworm that hosts a methanotrophic symbiont. Within bivalves, some symbionts use sulfide; others use the more oxidized and less toxic forms of sulfur, including thiosulfate or elemental sulfur. Several vent mussel species exhibit a dual symbiosis, harboring both methanotrophs and sulfur oxidizers. This diversity of symbiont capabilities within individuals increases metabolic flexibility and thus the range of environmental conditions under which the mussels may thrive.

Episymbiotic bacteria also occur in well-known associations with certain invertebrates. One of the best examples is the bacterial “fur coat” of the pompeii worm, *Alvinella pompejana*. This large polychaete worm lives in galleries on the sides of black smoker chimneys and experiences one of the steepest gradients of temperature along its body length of any invertebrate (40–50 °C). The dorsal surface of *A. pompejana* is

colonized by a morphologically diverse consortium of microorganisms, including large filamentous bacteria visible to the naked eye. The anatomical relationship between bacteria and worm is exquisite in its complexity, but the functional role of the members of the consortium remains unclear. Both trophic and detoxifying roles have been suggested. Episymbiotic, chemoautotrophic bacteria are also known from the chitinous cuticle of vent shrimp, *Rimicaris exoculata*. In this instance, the bacteria are thought to contribute to the diet of the shrimp; they are also likely to play some role in sulfide detoxification. Molecular characterization of the shrimp episymbionts shows them to be a single phylotype that matches the phylotype of the dominant free-living microbial species associated with the sulfide minerals on which the shrimp lives.

While there is much known and far more to be learned about microbial diversity at the interface between vent fluid and seawater, recent speculation about a vast, deep subsurface biosphere has fueled efforts to tap into the fluid-filled voids of the upper ocean crust. Efforts to understand microbial abundance, diversity, and function within such a biosphere may yield ancient lineages or otherwise novel species adapted to unusual conditions.

Invertebrate Diversity

It is the lush, gardenlike accumulations of invertebrate biota that make hydrothermal vent ecosystems a prized subject for television documentaries. Tubeworms often star in the title role, with clams and mussels as supporting actors, but this view of a simple ecosystem is little more than a Hollywood gimmick for audiences with short attention spans. The idea that vent systems have low invertebrate diversity is both pervasive and potentially misleading and is in large part due to the paucity of quantitative studies of diversity at vents. There is also a widespread failure to scale diversity measures at vents to the truly minute global acreage of vent habitat compared to extensive areas of soft-sediment deep sea or terrestrial rain forest, where diversity is so celebrated. These cautionary notes aside, there is an *a priori* reason to expect that diversity at vents might be low: Sulfide is a potent toxin, poisoning a major enzyme system of cellular respiration (cytochrome c oxidase) and bringing to a halt the aerobic production of ATP. Multicellular organisms that live at vents all must have some means of avoiding sulfide toxicity. This requirement may be a fundamental determinant of higher order invertebrate diversity at vents—only those groups that have efficient sulfide detoxification systems can occur where sulfide is present.

If we consider diversity at the phyletic level, vents are depauperate in several marine phyla normally found in the deep-sea benthos, including Porifera, Echinodermata, and the lophophorates (Phoronida, Bryozoa, Brachiopoda). The scarcity of sponges (Porifera) and echinoderms is attributed to the lack of excretory and blood vascular systems in these groups and a consequent inability to tolerate elevated levels of sulfide or other toxic compounds associated with hydrothermal vents; where these phyla are represented at vents, the animals are associated with the periphery of a vent field or other circumstances where sulfide levels are likely to be low (as in a waning vent site). The colonial motif and asexual reproduction are

also apparently unsuccessful at vents. Colonial coelenterates such as gorgonians, antipatharians, and hydroids are common animals of the deep sea but so far are virtually unknown at vents. An exception is a colonial siphonophore (distantly related to the Portuguese Man o' War) that is often found in large numbers at dying vents.

A number of hypotheses have been put forth to explain the absence of colonial organisms at vents, including intense competition and the ephemerality of vents, which may preclude any advantage of vegetative reproduction. Colonial organisms would also be at a disadvantage by virtue of the connectivity between individuals, since exposure of one individual within the colony to sulfide jeopardizes the aerobic metabolism of the entire colony. Encrusting colonial species are difficult to posit, because the vent effluent is buoyant and would tend to lift off recruiting polyps. Further, if established, an encrusting species could cap the flow, resulting in either diversion of the flow to less resistant paths or pooling of the flow with concomitant, life-threatening elevation of sulfide concentrations and temperature. While strategies to cope with these kinds of physical and chemical challenges to colonial organisms are not inconceivable, they have so far not been observed.

Origins of Vent Invertebrate Taxa

The majority of species that occur at vents (~90%) are known only from vents. This high degree of endemism is difficult to prove, given the lack of effective means of (and interest in) collecting organisms from nonvent, deep-sea basalts. Nevertheless, it is a distinctive fauna. Where does it come from? There is no single source. Some species belong to nonvent deep-sea genera (e.g., the squat lobster, *Munidopsis lentigo*); others have closest relatives among the shallow-water invertebrates (e.g., the polychaete *Ophryotrocha*). Several species, notably symbiont-containing invertebrates (tubeworms, clams, and mussels), have closest alliances to species known from other chemosynthetic ecosystems, such as brine and hydrocarbon seeps and whale skeletons. Some vent families (e.g., scale worms in the polychaete family Polynoidae) are broadly represented in the marine environment. Still others appear to be specialized taxa, known only from hydrothermal systems—the polychaete family Alvinellidae is a good example. Finally, some species appear to be most closely related to ancient Paleozoic or Mesozoic taxa, relict lineages that have found refuge in hydrothermal systems. These include several stalked barnacle species and an archaeogastropod limpet. Some taxa routinely found at vents have been hugely successful, undergoing substantial radiation. These include the siphonostome copepods, the archaeogastropod limpets, and the polynoid polychaetes; within each of these groups there are now dozens of described species.

Biogeography

When vents were first discovered in the eastern Pacific, there was much speculation about how many vents there might be, where they were, and whether the fauna would be cosmopolitan. We know now that there are likely to be hundreds, if

not thousands, of hydrothermal vent fields along the mid-ocean ridge system and that they can be found in every ocean basin. Furthermore, we know that the fauna is not cosmopolitan. Distinct biogeographic provinces occur, defined in part by the tectonic fabric and history of the ocean plates. Along a continuous ridge system such as the East Pacific Rise, which stretches from the head of the Gulf of California down to high latitudes in the Southern Hemisphere, the fauna of the hydrothermal vents undergoes subtle changes. The same species of tubeworms, mussels, and clams generally dominate the biomass (mussels are absent from the northernmost locales), but the details of their relative abundance change from site to site. These dominant taxa (especially the tubeworms and mussels) are autogenic bioengineers, creating complex three-dimensional habitat that becomes occupied by countless individuals of crustacean, mollusk, and polychaete species. We know little about how the ranges of the hundreds of smaller invertebrate species that live in association with these autogenic taxa vary along the length of the East Pacific Rise nor of how these ranges relate to the life history characteristics of each species.

At its northern limit in the Gulf of California, the East Pacific Rise goes terrestrial as a strike-slip fault (the San Andreas), reemerging in the submarine environment off northern California as the Mendocino fracture zone. From there, the spreading ridge axis between the Pacific and North American plates heads northward as the Gorda, Juan de Fuca, and Explorer Ridge systems. The vent fauna of these northern ridges is distinct from that of the East Pacific Rise at the species level, but there are alliances at the generic and familial levels. Verena Tunnicliffe (University of Victoria) notes that at one point in the geological history of these ocean plates, the East Pacific Rise and northern ridges were one continuous system. Overriding by the North American Plate was a vicariant event, bisecting the ridge system and resulting in subsequent development of the vent faunas in isolation and of two distinct, formerly related, biogeographic provinces.

Other biogeographic provinces are known: Deep-sea hydrothermal vents at back-arc spreading centers associated with western Pacific microplates support a distinctive invertebrate fauna at the species level, although at higher taxonomic levels, affiliation to the two eastern Pacific biogeographic provinces is patent. This affiliation may be related to the direct link that existed between the eastern and western Pacific via the now extinct Kula Ridge more than 40 million years ago. Deep-sea vents along the Mid-Atlantic Ridge support an even more disparate group of species and genera. Based on biogeographic characterization of these four major geographic regions, we expect that ridge systems in unexplored ocean basins (the Arctic and the Indian Oceans in particular) will yield hundreds of new species. Exploration and discovery remain hallmarks of the study of diversity and biogeography at vents.

Gene Flow and Genetic Diversity

Deep-sea hydrothermal vents on midocean ridges are distributed as linear, insular, and ephemeral arrays of endemic species. To persist in the face of certain local extinction, survival of

a species in any region is only possible where propagules can disperse to other vents. An understanding of gene flow along these arrays is essential if we are to understand species distributions and speciation processes at vents. Two basic models of gene flow, borrowed from island biogeography, have been applied to genetic data from vent populations. In the “stepping-stone” model, gene exchange occurs locally, between neighboring populations, and genetic exchange decreases with increasing distance. In the “island” model, there is thorough mixing of gene pools over a regional scale. Vent taxa conform to no single model of gene flow. Tubeworms on the East Pacific Rise, for instance, appear to follow a stepping-stone model, while mussels on the same ridge follow the island model. Still other species display a ridge-based isolation model, where topography of the ridge system (e.g., deep east–west fracture zones that offset the shallower north–south-trending ridge) creates a genetic filter. Studies of genetic diversity in vent systems by Robert Vrijenhoek (Monterey Bay Aquarium Research Institute) and his students highlight the significance of the number of populations in sustaining genetic diversity: vent species with abundant populations have higher genetic diversity than species with fewer populations. Genetic diversity in vent organisms (measured as percentage of polymorphic loci within a population) is also correlated with the order of establishment of species at nascent vents, with early colonists having double the genetic diversity of later colonizing species.

Biodiversity

For two decades, basic community descriptors of species richness and diversity eluded vent ecologists. Sampling was qualitative, with uneven efforts, and typically resulted in lists of species for vent sites without regard to distributions within specific microhabitats. An exception is the work of Fred Grassle (Rutgers University), who compared diversity of soft-sediment vent infauna with infaunal diversity in the surrounding soft-sediment, nonvent environment. His quantitative data demonstrated that diversity in vent muds is low compared to the relatively high species diversity of the “normal” deep sea. Further, at vents, one or two species account for 70–90% of the infaunal individuals, whereas in the nonvent deep sea, abundances are more evenly distributed among species, with the most common species making up less than 20% of the total. Similar results were found in studies by others of soft-sediment meiofauna. But soft sediments are the exception rather than the rule for deep-sea hydrothermal vents.

What about hard-substrate biodiversity at vents? Species richness measured at a site on the Mid-Atlantic Ridge based on replicate samples within a single vent habitat (mussel beds) and species–effort curves has been compared to values obtained using a comparable sampling effort at an intertidal mussel bed in south-central Alaska. The intertidal, photosynthetic site supported more than twice as many species than the deep-sea chemosynthetic site, consistent with the idea that diversity at vents is low. But diversity in intertidal mussel beds is well-known to be geographically variable; some intertidal mussel beds (e.g., along the coast of Japan) are reported to

have species richness values comparable to what is found at the Mid-Atlantic Ridge vent site.

Vents allow us to study patterns of regional diversity over different scales of spatial frequency of habitat and in the absence of confounding climatic and anthropogenic effects. The Mid-Atlantic Ridge is a slow-spreading ridge system, with vents spaced relatively far apart (hundreds of kilometers). Diversity is predicted to be higher on faster spreading centers where vents are more closely spaced. With the same sampling methods as used at the Mid-Atlantic Ridge vent site, diversity has been measured at two vent fields on the ultrafast spreading southern East Pacific Rise. Diversity at these vents is comparable to that of the Alaskan intertidal mussel bed. Thus, whether one considers diversity at vents to be high or low depends only on which end members one chooses to compare.

Of theoretical importance is the fact that patterns in diversity at midocean ridge hydrothermal vents may be controlled by fundamental properties associated with plate tectonics and volcanism that determine the spatial frequency of vent habitat. Where vents are closely spaced, the likelihood of extinction is relatively low, and species tend to accumulate. Where vents are far apart, a premium is placed on effective dispersal, extinction becomes much more likely, and allopatric speciation is enhanced. This hypothesis leads to the prediction that slow-spreading systems, with distant vents, support a greater number of biogeographic provinces, each with lower species diversity than fast-spreading systems with closely spaced vents.

Area – spreading rate relationships have also been proposed as controls on species diversity at vents. In general, the well-known area – species relationship is driven by increasing numbers of habitats with increasing area. While presumably relatively unimportant when comparing diversity within habitat types (e.g., mussel beds), the increasing vent area (and, by inference, habitat diversity) with spreading rate should contribute to increasing species diversity within vent fields. Quantitative assessment of species diversity within all representative microhabitats of vent fields and measures of areal extent of fields along ridges of different spreading rates is not a tractable approach at this time.

Glossary

Benthic Located on the bottom of a water body, or pertaining to bottom-dwelling organisms.

Biological diversity The variety of different forms of life on earth, usually considered to include variety at all levels of biological organization from genetic variation to variety seen in species, populations, communities, and ecosystems.

Bog An acidic peatland that receives all water inputs from the atmosphere and hence has low pH (usually 3.4–4.6), low alkalinity, and negligible concentrations of base cations in surface waters; typically dominated by mosses of the genus *Sphagnum* and other plants able to tolerate low pH and low nutrient availability – that is, members of the heath family (Ericaceae).

Calcareous fen A term variously used for wetlands with high calcium carbonate in water and soils. In the strict sense, the term refers to peat-accumulating wetlands with surficial deposits of calcium carbonate and a distinctive flora of calciphilic species. These wetlands typically develop where substantial amounts of cold, calcium-carbonate rich groundwater discharge to the surface.

Detritivores Organisms that consume dead plant or animal material.

Emergent vegetation Rooted plants that tolerate saturated or flooded soil but not extended periods of submersion.

Floodplain Broad, flat areas adjacent to rivers and streams that become inundated during floods.

Hydrologic regime The aggregate set of variables describing the behavior of water in wetlands, including water depth, magnitude and frequency of water level fluctuations, seasonal pattern of water fluctuations, direction and velocity of water flows, and water residence time.

Hydrophytes Plants capable of growing and persisting in saturated or flooded soils.

Littoral The shoreline zone where sunlight penetrates to a wetland's substrate and supports rooted plant growth.

Macroinvertebrates Organisms lacking backbones and generally visible to the human eye.

Marsh A wetland dominated by herbaceous species of plants (e.g., cattails, sedges, grasses, floating ferns) and typically occurring on mineral soils. Floating-leaved and

submerged species of plants dominate the parts of marshes that grade into open water. Although the surface layer of some marsh soils may consist of shallow accumulations of organic matter over mineral soils, the depth of this layer is usually less than the minimum required for the site to be classified as peatland.

Peat A type of soil formed from accumulation of the remains of dead plants, with high organic matter content (minimally 20% and as high as 90% by dry weight) and depth greater than 30 to 40 cm. Peat forms in some wetlands because anoxic conditions, low pH, low temperatures and short growing seasons, or plant tissues highly resistant to decay prevent rates of decomposition from keeping up with rates of organic matter production.

Peatlands Wetlands in which dead organic matter accumulates to form peat more than 30 to 40 cm deep; typically includes bogs, poor fens, and rich fens but some swamps also occur on peat.

Poor fen An acidic peatland similar to a bog but having a somewhat higher surface water pH (4.3–5.8) because it receives some groundwater or surface water in addition to precipitation; typically dominated by *Sphagnum* mosses or sedges. But for the presence of distinctive poor-fen indicators, vegetation may superficially resemble bog vegetation or sedge-dominated rich fens that lack *Sphagnum*.

Rich fen An alkaline peatland that receives significant inputs from groundwater or surface water; typically having surface water pHs > 6.0, higher alkalinity, and distinctly higher concentrations of base cations than bogs and poor fens; dominated by brown mosses (true mosses, largely of the Amblystegiaceae) and small sedges.

Species richness The number of different species in a specified area.

Submerged vegetation Plants that grow and reproduce while completely submerged.

Swamp Wetlands dominated by woody species. Although the term has been variously used, it is used here in the restricted sense of forested wetland, either on mineral soils or peat. However, while many peatland ecologists classify forested fens on deep peat as swamps, they would not call a bog forest a swamp.

Diversity of Wetland Ecosystems

Wetlands, and the organisms adapted to these unique environments, are as diverse as the myriad combinations of

climate, topography, and geology that cause different types of wetlands to form. By definition, wetlands are ecosystems whose physical, chemical, and biological characteristics are determined by the constant or recurrent presence of water at

or near the soil surface. Beyond this commonality, however, lies a seemingly infinite number of ways in which climate and landscape features combine to create wetlands with different: magnitudes and seasonal patterns of water level fluctuation, paths and rates of water movement, soils, water chemistry, nutrient status, and species composition. Out of this landscape diversity rises the large number of different types of wetland ecosystems seen worldwide.

Wetlands occur on every continent except Antarctica and in every climatic regime. The best available estimates indicate that they cover only between 4 and 6% of the Earth's land surface. Within this relatively small area, however, an astonishingly high number of different wetland ecosystem types occur. A recent global summary (Mitsch, 1994) hints at this diversity when it describes the world's wetlands in terms of coarse-scaled differences in climatic setting, geomorphologic setting, and major wetland type. According to that summary, wetlands "are found (a) in humid, cool regions as bogs, fens, and tundra; (b) along rivers and streams as riparian wetlands, seasonally flooded forests, and back swamps; (c) in the delta's of the world's great rivers; (d) along temperate, subtropical, and tropical coastlines as salt marshes, mudflats, and mangrove swamps; and (e) in arid regions as inland salt flats, seasonal playas, and vernal pools". They also are found as (f) marshes, wet meadows, and swamps in depressions that occur in a variety of landscapes and climatic settings; (g) marshes, wet meadows, and swamps on extensive flat areas where the land surface slope is minimal and climate is humid; and (h) marshes, bogs, and fens along the shores of lakes in many climatic regions. Wetlands even occur on (i) slopes as blanket bogs, seepage fens, and vegetated springs.

Finer-scaled differences in climate, geomorphologic setting, and biogeographic region yield an even greater diversity of wetland ecosystem types. Mangrove swamps, for instance, do not exhibit uniform species composition worldwide. The mangrove ecosystems of the Indo-western Pacific have a far greater number of plant species than do the mangrove swamps of Central America, and they certainly should be considered different ecosystems for conservation purposes. The nutrient-poor sawgrass (*Cladium jamaicense*) marshes of the Everglades differ profoundly from the nutrient-rich giant reed grass (*Phragmites australis*) marshes of the Camargue in France's Rhone delta in land form, water chemistry, vegetation, and animal life. Neither of these marsh ecosystems bears much similarity to the thousands of small marshes that dot the prairie pothole region of Canada and the north central United States. The montane cushion-plant herbaceous bogs of Chile contain flora and fauna quite distinct from that of the *Sphagnum* moss-dominated bogs of the Northern Hemisphere, and from the domed bogs of Sarawak. The shore pine (*Pinus contorta*) bogs of Vancouver Island's Pacific coast contain many plant species not seen in Canada's continental bogs. Seasonally flooded forests along rivers include ecosystems as dissimilar as the sometimes monotypic palm swamps of South America, the moderately species-rich hardwood swamps of the southeastern United States (Figure 1), and the highly species-rich *varzea* forests of the Amazon basin. Forested wetlands (Figure 2) also include those occurring on steep windward slopes of Puerto Rico's Luquillo Mountains where annual precipitation as high as 5000 mm keeps the clayey

Figure 1 Southern deepwater swamp, Congaree National Monument, South Carolina, USA.

Figure 2 Forested wetland in upstate New York, USA.

soils continuously saturated. In Finland, where about one-third of the land is peatland, at least 30 different mire types are recognized. Some of the bogs and fens of Ireland and Scotland, Scandinavia, Finland, Alaska and Canada, the former Soviet Union, and Maine form intricately patterned peatlands, some of the most unique land forms on earth.

Classification of the Major Wetland Ecosystems of the World

Because wetlands take so many forms, occur in many different physiographic and climatic settings, and form part of the history and culture of many regions of the world, their diversity is not easily cataloged. Different regional and colloquial names for them abound, as do formal classification systems. Different common names may refer to the same type of wetland with similar species, while the same name may be applied in different parts of the world to wetlands with quite different species. For example, the terms mire, moor, muskeg, and peatland all refer to similar types of wetlands with similar plant growth forms and many common species. On the other hand, the term swamp is used for a variety of forested wetlands in the United States but for areas dominated by giant

reed grass (*Phragmites*) and other herbaceous species in parts of Europe and Africa. Fens dominated by woody species may be called swamps, forested fens, or forested wetlands. In the strictest sense, bogs are peat-accumulating wetlands that receive water only from precipitation. However, the term also is applied to poor fens, which superficially resemble true bogs, and more loosely to any wet vegetated environment that offers less than firm footing.

Numerous formal classifications of the different types of wetlands have been developed. They give some indication of the vast diversity of wetland ecosystems but cannot be used to enumerate that diversity. Because they have been developed for different purposes and from different scientific perspectives, they vary in the criteria used for classification and in the level of resolution to which they classify wetlands. Nonetheless, the existence of literally dozens of wetland classifications worldwide implies the existence of such a high diversity of types that they must be grouped into similar classes for practical reasons of inventory, mapping, management, and scientific communication.

The high diversity of wetland ecosystems also is revealed by considering the many different bases for wetland classification: geomorphologic setting in the landscape, genesis (how they formed), shape or form (e.g., surface morphology, basin morphometry, morphology of the underlying mineral terrain), hydrology (e.g., flooding frequency and duration), sources of water supply, physiognomy of the vegetation, species composition of the vegetation, soil type, water chemistry, and various combinations of these factors. Given that each of these variables represents not a single factor but rather a continuum, the extremely large number of possible combinations becomes apparent. Thus, most classifications in wide use today are broadly based, interdisciplinary, and hierarchical (i.e., consisting of several nested levels with increasing detail only at lower levels in the hierarchy). Species composition, the basis for diversity within wetlands and the focus of many older classifications, is usually not a defining characteristic except at the lowest levels in current classifications. Rather, similarities in hydrology and geomorphology are more likely to form the highest levels of classification, reflecting the importance of the interaction of water with the landscape in determining the biotic characteristics of wetlands.

Nonetheless, the terms bog, fen, marsh, and swamp persist in both scientific and popular literature because of their long history of use and the powerful images they evoke. These terms are not distinguished primarily on the basis of geomorphology or hydrology; nor are they distinguished on any single criterion, nor used consistently. Perhaps the key distinction among them in terms of species diversity is their source or sources of water, which determine hydrologic regime and water chemistry. Greater surface water inputs generally lead to greater water level fluctuations and higher concentrations of base cations and nutrients in marshes and swamps on mineral soils than in bogs and fens. In this chapter, these terms follow current American usage (see Glossary).

The current classification systems used in the United States (Cowardin *et al.*, 1979) and Canada (National Wetlands Working Group, 1997) reveal much about the diversity of wetlands in these two countries. For example, the U.S. classification is hierarchical, recognizing 5 major wetland systems

and 10 *subsystems*, each of which is divided further into 4 to 8 *classes*. A *system* is defined as “a complex of wetlands and deepwater habitats that share the influence of similar hydrologic, geomorphologic, chemical, or biological factors” (Cowardin *et al.*, 1979, p. 4). The five systems are the marine, estuarine, riverine, lacustrine, and palustrine. The term *class* “describes the general appearance of the habitat in terms of either the dominant life forms of the vegetation or the physiography and composition of the substrate—features that can be recognized without the aid of detailed environmental measurements.” Classes can be further divided into *dominance* types based on dominant plant species for vegetated sites or on the dominant sedentary or sessile animal species where vegetation is not the dominant cover. Special *modifiers* are used for water regime (type and duration of flooding), water chemistry, soils, and human alterations (e.g., excavated, impounded, diked). Fifty-five classes emerge before one ever gets to the level of dominant species, water regime, or water chemistry.

Most of Canada’s wetlands fall within just one system (palustrine) of the U.S. classification. Canada’s classification differentiates many types of palustrine wetland, especially peatlands. This classification also is hierarchical but with just three levels: *class*, *form*, and *type*. Five *classes* are recognized: bog, fen, marsh, swamp, and shallow water. *Forms* are defined on the basis of surface morphology of the wetland, position in the landscape, morphology of the underlying terrain, tidal effects, and proximity to surface water bodies. The Canadian system recognizes 16 bog forms and 4 subforms, 12 fen forms and 7 subforms, 8 marsh forms with 18 subforms, 8 swamp forms with 19 subforms, and 5 shallow water forms with 24 subforms. The 18 *types* based on the general physiognomy of the vegetation (e.g., hardwood treed, coniferous treed, low shrub) modify these 121 forms and subforms. Differences in species composition are left to individual users.

Only the wetlands of western Europe are as well documented as those of the United States and Canada. Specific sites on other continents have received considerable attention but, with few exceptions, comparative regional treatments began to emerge in the English language only 15 years ago, with most appearing since 1990 (see References). The exceptions include Chapman’s books—for example, *Salt Marshes and Salt Deserts of the World* (1960), *Mangrove Vegetation* (1976), and *Wet Coastal Ecosystems* (1977). However, despite the general lack of scientific studies in many areas of the world, as of 1991, 62 countries from all continents had signed the Convention on Wetlands of International Importance Especially as Waterfowl Habitat (Ramsar Convention) and had designated 527 sites covering more than 30 million ha as being of international importance. Five international wetland symposia have been organized since 1980 by INTECOL (The International Society of Ecology), with a sixth planned for the year 2000 in Quebec City.

Major Regional Wetland Ecosystems

Efforts to classify wetlands into unique entities often obscure, either spatially or temporally, critical connections among parts of what might be viewed as integrated ecological systems.

For example, various classification systems segment the great delta of the Mississippi and Atchafalaya rivers into many types of floodplain forest, freshwater marsh, salt marsh, streams, and lakes. They assign each prairie pothole in the prairie region of the United States and Canada to one of about 20 classes of prairie wetlands. The mangrove forests of Central America are made to seem distinct from the adjacent beds of sea grasses. Functionally, however, these diverse wetlands are linked and might be better viewed as major regional wetland ecosystems. Water, sediments, plant propagules, fish, birds, other animals, genetic material, and pollutants move among them. One type changes through time to become another. Diversity emerges in both space and time from the components as well as their interconnectedness.

In fact, prior to human modification of them, most wetlands existed as complexes of several different types functioning as integrated systems linked by movements of water, sediment, nutrients, plants, and animals. The vast rain-fed and riverine floodplains that form the Sudd in southern Sudan, for example, consist of a complex and dynamic mix of different types of grassland (e.g., *Echinochloa pyramidalis* or *Hyparrhenia rufa* dominated), wild rice marshes (*Oryza longistaminata*), woodlands (*Acacia seyal* or *Balanites aegyptiaca* dominated), and open water that cover more than 45,000 km². The great floodplain of the Orinoco River and its tributaries form a nearly 10-million ha wetland complex of streams, ponds, shallow oxbow lakes, riverine forest, marshes, and seasonally-flooded palm (*Copernicia tectorum*) savannas and grassland in Venezuela and eastern Columbia. The eastern shore of Lake Ontario, New York, is bordered by a 17-mile long interconnected system of streams, shallow ponds, marshes, fens, and shrub swamps. Most temperate zone estuaries include freshwater, brackish, and saltwater marshes along with tidal creeks and mudflats. Mangrove swamps, saline lagoons, sea grass beds, and coral reefs form interconnected systems along shallow coasts in subtropical and tropical regions.

These complexes, or assemblages of wetlands within regions, represent another level of wetland diversity that only partially remains today. Current classification systems do not capture such regional ecosystems, though clearly they exist. Many people recognize wetland complexes such as the Everglades and the Prairie Pothole Region as regional ecosystems. Classification systems, however, only recognize hierarchy in types, not in assemblages of wetlands within regions. Current efforts by conservation organizations and government agencies to move to ecoregional mapping attempt to overcome this limitation.

Continental and Regional Diversity

Climate and geomorphology, along with biogeographic factors, control the diversity of wetlands on different continents and in different regions. Wetland development is promoted where precipitation annually exceeds evapotranspiration on a long-term basis. In such climates, wetlands develop in a number of landscape settings, including depressions in the land surface, areas where minimal land surface slope slows surface water runoff, along breaks in the slope of the land surface, and even on slopes if precipitation greatly exceeds

evapotranspiration. In semiarid, arid, and desert climates, wetlands occur far less frequently, but they are found (a) in areas with depressions or lowlying land along rivers or coasts where runoff converges from extensive uplands or mountains, (b) along coasts regularly inundated by tides, (c) in areas where permafrost or other impermeable layers below ground prevent or slow infiltration of surface water, and (d) in spring-fed oases.

In addition to topographic variation, variation in the composition and stratigraphy of surficial geological deposits promotes diversity in the types of wetland that occur within a region. The composition of subsurface materials plays a major role in determining the chemistry of water entering wetlands, and thereby the plant species composition of wetlands. For example, wetlands occurring in regions dominated by limestone deposits tend to have high-pH waters rich in base cations that promote the growth of distinctive rich fen vegetation. In contrast, waters draining areas with granitic bedrock tend to be low in pH and base cations; such areas more frequently contain bog-like vegetation. Areas with thick deposits of glacial till can contain a mix of rock types that, in turn, may support a variety of wetland types. A diversity of types in a given region also is promoted where surface topography and subsurface stratigraphy of geological deposits produce groundwater flow paths of varying lengths. Wetland water chemistry is strongly influenced not only by water source but also by the length of groundwater flow paths that enter the wetland and the number of different groundwater flow systems that feed the wetland. Different flow systems may contribute water with different chemistry because the water originates from different geological deposits. If the water originates from the same geological materials, longer flow paths may yield higher concentrations of solutes because longer flow paths generally correlate with longer groundwater residence time (i.e., longer contact time with geological materials).

Biogeographic factors also influence the number of wetland types occurring in different regions and continents. Aquatic plants generally are known for their remarkably wide geographic range, but many species have smaller ranges determined in part by biogeographic factors (i.e., the climatological, geological, glacial, and floristic history of a region). The distributions of these more restricted species help define distinctive biogeographic regions that contain wetlands with species compositions unlike those from other biogeographic regions. For example, shallow ponds that support many species of the Atlantic Coastal Plain flora might be classed broadly as emergent marshes, but this would miss their unique contribution to the diversity of North American wetlands. The flora of these coastal plain ponds, which has an unusual abundance of rare and uncommon species, bears little resemblance to the emergent marshes of other biogeographic regions.

While no systematic comparison has been made of wetland ecosystem diversity in different regions, the factors controlling regional wetland diversity are understood. All other things being equal, regions with the greatest climatic and geomorphologic variation are likely also to contain the highest diversity of wetland types. If wetland types are defined to the level of plant species composition, then biogeography enters into the equation. Thus, continental diversity will vary as a

function of the number and combination of different climatic, geomorphologic, and biogeographic regions occurring on that continent.

Diversity Within Wetland Ecosystems

Plant Species Richness within Wetlands

At the regional and global scale, wetlands clearly exhibit high diversity of types and an associated high diversity of plant species. Within-habitat (or *alpha*) diversity, and between-habitat (or *beta*) diversity, however, is highly variable among wetlands. Wetlands include some of the most species-rich plant communities in the world, as well as numerous examples of extensive stands dominated by a single species. Familiar examples of single-species wetlands include mangrove swamps, tidal marshes of salt marsh cordgrass (*Spartina alterniflora* or *Spartina patens*), cattail (*Typha* spp.) marshes, and papyrus (*Cyperus papyrus*) swamps. Species-rich herbaceous communities include calcareous fens with as many as 20 to 30 species of vascular plants and bryophytes per square meter. Intermediate examples include abandoned beaver ponds with 3 to 12 species per square meter and a range of coastal wetlands (bottomland hardwoods, wet prairies, fresh marsh, and salt marsh) from the southern United States with 1 to 17 species per square meter.

Change in plant species composition across gradients within wetland sites depends on the amount of change that occurs within a site in the physical and chemical variables controlling species distributions. A single small depression may encompass a wide range of water depths and the associated changes in species composition. Although adjacent zones may share some species, the deep-water end of the gradient, which may be dominated by floating or submerged species, shares no species with the sedge- and forb-dominated wet meadow zone at the other end of the gradient. Depending on the slope and width of the floodplain, wetlands along major rivers may include areas that experience very different frequencies of flooding and consist of very different plant communities, from the open water and marshes of backwater sloughs to hardwood-dominated forests along natural levees. Erosion and deposition of sediments within the floodplain create surfaces of varying ages that support plant communities of different successional status and composition. Much of the species diversity in the Peruvian Amazon has been attributed to the heterogeneity created by long-term patterns of erosion, deposition, and plant succession.

In other wetlands, environment changes little over relatively large distances, for example, where the accumulation of peat has filled in basins and minimized topographic changes. Though the presence of hummocks and hollows introduces small-scale heterogeneity, mean water depth, pH, and nutrient availability change little as one moves across the bog surface. Plant species composition in plots spaced at great distances, but at equivalent microtopographical elevation, may be quite similar.

Although many studies have examined plant species richness in small plots, systematic comparisons are difficult to make because plot size and sample number vary among

studies. Given that species richness is known to increase with increasing sample area, conclusions cannot be drawn about relative richness among samples if sample areas are not equal. Nonetheless, some general statements can be made. First, the number of plant species present generally decreases as water depth and frequency of saturation or flooding increase. For example, in his study of Wisconsin plant communities, Curtis (1959) reported that the average number of species per stand ranged as follows: 7 in stands of submerged aquatics, 11 for emergent aquatics, 28 to 29 in sedge meadows, 44 in wet prairie, and 62 in wet-mesic prairie.

Second, the effect of moving water on diversity depends on flood velocity, magnitude, and frequency. Some degree of disturbance from flooding increases diversity by removing live biomass and litter, thereby creating openings for germination of new species. Extreme or very frequent flooding, however, lowers diversity. Few species can withstand both the high stress of extended periods of anoxia and the frequent disturbance of biomass removal.

Third, the vegetation of saline wetlands tends to be less species-rich than freshwater wetlands. For example, coastal salt marshes of the eastern United States rarely contain more than two species in 0.25-m² plots (Figure 3). Plots of comparable size in freshwater herbaceous communities frequently contain 10 or more species. Increasing the plot size in salt marshes adds few species but is likely to significantly increase species number in many types of freshwater wetlands. For example, the number of vascular and bryophyte species in rich fens in New York increases from about 20 in 1-m² plots to 40 in 25-m² plots to 65 in 100-m² plots (Figure 12).

Fourth, in the temperate and boreal zones, *alpha* diversity generally increases across the range of peat-land types from bog to rich fen for vascular species. Continental raised bogs in eastern North America may have only 20 to 25 vascular species per site, one of the most impoverished vascular floras in North America. Rich fens may contain as many as 140 vascular species at a single site. The bryophyte diversity also tends to increase from bogs to rich fens in eastern North America. Continental raised bogs usually have fewer than 20 species of bryophytes in 100 m² while rich fens usually have between 20 and 60 bryophytes in a similar-sized plot. However, Vitt and others (1995) reported that bryophyte diversity in peatlands of continental western Canada could be similar for bogs and

Figure 3 Salt marsh in southern New Jersey, USA.

fens. Species richness in larger plots (2500 m²) ranged from about 5 to 24 in bogs and poor fens and from about 5 to 28 in rich fens. Thus, even though the highest species richness was found in extreme rich fens, any individual bog could contain as many species of bryophytes as a rich fen. At the landscape scale, rich fens are distinctly more species rich than bogs and poor fens. Because their species composition varies more among sites, rich fens have greater diversity when an entire region is considered. In both Britain and continental western Canada, bogs have only about half the number of bryophyte species as fens.

Fifth, relative to the landscapes in which they occur, many types of wetlands appear to be islands of diversity. Fens in northeastern Iowa support 28% of the regional and 18% of the total state flora even though they currently cover only 0.01% of the land surface. Boreal old-growth swamp forests constitute only 5% of Sweden's forest land area but harbor more than half of all vascular forest plant species found in Sweden and about a third of the total Swedish boreal flora of bryophytes. Almost a third of the federally listed threatened and endangered plant species in the United States are wetland dependent. Furthermore, for some types of wetlands, rare and uncommon plant species tend to be associated with the most species-rich sites.

Finally, latitudinal patterns in plant species diversity of wetlands do not appear to parallel those for terrestrial environments. In sharp contrast to terrestrial habitats, wetlands in the tropics are not necessarily more species rich than those in the temperate and boreal zones. According to Ellison 2004, the mangrove swamps, palustrine forested wetlands, palm swamps, and hardwood swamp forests of Central America all exhibit low species diversity. On the basis of a comparison of representative aquatic families and aquatic habitats, Crow (1993) also concluded that aquatic plant diversity was higher in both warm and cool temperate latitudes than in the tropics. On the other hand, some tropical wetlands can be highly diverse. Ellison 2004 reported high plant species richness (292 species of 0.5 m in height or greater) in riparian forest fragments in Belize. Additional systematic and standardized studies are needed to address this issue.

Major Groups of Wetland Animals

In terms of abundance, biomass, and species richness, macroinvertebrates are the most important wetland-dependent animals in freshwater wetlands. Four groups—the insects, mollusks, crustaceans, and annelids—make up the majority. The aquatic insects are the most functionally and taxonomically diverse, and include forms that occur throughout all habitats (the bottom, deep waters, and shallow, vegetated areas) in most wetlands. The midges (Chironomidae, Diptera) constitute perhaps the most widespread group of aquatic insects, and larval forms of midges typically represent the most abundant macroinvertebrates in wetlands. Other ecologically important, widespread groups include the mosquitoes, dragonflies and damselflies (Odonata), mayflies (Ephemeroptera), caddisflies (Trichoptera), stoneflies (Plecoptera), craneflies (Tipulidae), and water beetles (e.g., Corixidae, Belostomatidae, and Notonectidae). Among these groups,

only the water beetles are entirely aquatic; members of other groups typically have aquatic larval stages that undergo a synchronized transformation ("hatch") into adult forms, which may live for periods ranging from 1 to 2 days (some mayflies) to weeks or months (many dragon-flies).

The mollusks include the many species of filter-feeding clams and herbivorous snails. The most widespread and common are fingernail clams. Larger clams and mussels are equally widespread but less common, although they are sometimes abundant along large rivers and lake fringes. Most large clams dwell on the bottom of wetlands, whereas the fingernail clams often occur in submerged vegetation. Snails also occur in many wetlands and live upon stems, stalks, and leaves of aquatic vegetation, and graze on epiphytes.

The crustaceans, like the aquatic insects, are commonly encountered throughout most freshwater wetlands. Especially common in open-water and upon aquatic vegetation are isopods and amphipods. In protected open water areas, small zooplankters, including cladocerans and copepods are abundant. Crayfish are common bottom-dwelling crustaceans in many wetland ecosystems. The last major group of aquatic invertebrates, the annelids (mainly oligochaetes), are not particularly diverse taxonomically. However, they can be extremely abundant in some wetlands, where they burrow in the wetland bottom or attach to aquatic vegetation.

Vertebrate animals represent another important component of the wetland fauna and include the amphibians, reptiles, fishes, birds, and mammals. The amphibians are composed of two main groups, the frogs and toads, and the salamanders. Most species of frogs and toads have complex life cycles that include an aquatic, usually herbivorous, larval stage adapted for rapid growth (the tadpole stage), and a terrestrial, carnivorous adult stage adapted for dispersal among wetlands (Figure 4). Their relative use of wetlands versus uplands varies among groups. For example, the major group of frogs in North America, the Ranidae, includes (a) members that may be mostly terrestrial but return to wetlands to breed and sometimes to overwinter (e.g., members of the leopard frog complex, e.g. *Rana pipiens*) and (b) other species (e.g., bullfrogs, *Rana catesbeiana*) that are primarily aquatic and typically leave wetlands only to disperse to new areas.

Figure 4 Frog and duckweed in freshwater marsh in upstate New York, USA.

Among North American salamanders, all are wetland dependent except for members of the Plethodontidae, although even this family includes the Desmognathinae, a large group of stream-associated species. In salamanders, wetland dependency ranges from strictly aquatic (e.g., mudpuppies (*Necturus*), hellbenders (*Cryptobranchus*), Conger eels (*Amphiuma*), and sirens (*Siren*)), to semiaquatic in groups that spend much of the growing season in wetlands but overwinter on land (e.g., newts (*Salamandridae*)), to primarily terrestrial species that return to wetlands only to breed (e.g., the vernal pool-breeding mole salamanders (*Ambystomidae*)).

In terms of numbers, species richness, and biomass, the majority of wetland fishes are small forage fishes. In North America, the primary groups are the killifishes (*Fundulus*), shiners (*Notropis*), sunfishes (*Lepomis*), and mosquito fishes (*Gambusia*). In deeper-water wetlands or wetlands connected to permanent water bodies, larger, bottom-feeding species occur, such as Ictalurid catfish (e.g., bullheads) and carp (*Cyprinus carpio*), as well as carnivorous species such as pickerel (*Esox*), perch (*Perca*), and bass (*Micropterus*, *Morone*).

Turtles are the most diverse group of wetland reptiles. Most turtles are highly aquatic and leave water only to lay their eggs and to disperse to new habitats. Commonly encountered, highly aquatic turtles in North America include the snapping turtle (*Chelydra serpentina*), mud and musk turtles (*Kinosternidae*), and softshells (*Trionychidae*). The Family Emydidae includes many other highly aquatic turtles, such as cooters, sliders, painted turtles (*Pseudemys* and *Chrysemys*), map turtles and sawbacks (*Graptemys*), and terrapins (*Malaclemys*), as well as other partially aquatic species that travel regularly among disjunct wetlands (e.g., spotted turtle (*Clemmys guttata*)) or that use wetlands only for hibernation (e.g., wood turtles (*Clemmys insculpta*)). Other wetland-dependent reptiles include the water snakes (e.g., *Nerodia*) that use wetlands primarily for feeding on fish, frogs, and crayfish, and rest above water on hydrophytes or on land at other times. Most wetland-dependent snakes are viviparous, that is, bear live young, and therefore do not undertake migrations to terrestrial habitats to lay eggs, as do turtles. Many other snakes, however, and some lizards, live primarily in uplands but feed opportunistically in wetlands (e.g., king snakes (*Lampropeltis*), rat snakes (*Elaphe*), and garter snakes (*Thamnophis*)).

Several large groups of birds occur nearly exclusively in wetlands. These include many carnivorous (mainly fish-eating) species, such as the loons (*Gaviidae*), herons and bitterns (*Ardeidae*), several waterfowl species (*Anatidae*), the kingfishers (*Alcedinidae*), terns (*Sternidae*), and several raptors (*Accipitridae*, e.g., ospreys (*Pandion haliaetus*)). Omnivorous groups include the grebes (*Podicipedidae*), many species of diving and dabbling ducks (*Anatidae*), cranes (*Gruidae*), rails (*Rallidae*), and gulls (*Laridae*). Primarily insectivorous species include the shorebirds (*Charadriidae*) and many songbirds. Unlike other wetland inhabitants, birds are highly mobile and often use disjunct wetlands seasonally or even daily (Figure 5).

The last group of wetland-associated vertebrate animals, the mammals, include few, wholly wetland-dependent species. Most prominent are rodents such as the muskrat (*Ondatra zibethicus*) and beaver (*Castor canadensis*). Other obligate wetland mammals include several primitive, carnivorous shrews

Figure 5 Foraging assemblage of scarlet ibis and barefaced ibis in the seasonally flooded grasslands of central Venezuela (Apure state). Photo by Mark Gregory.

(“water shrews” in the genus *Sorex*), some lagamorphs such as the swamp rabbit (*Sylvilagus aquaticus*) and marsh rabbit (*S. palustris*), and mustelids such as the river otter (*Lutra canadensis*). Wetlands are a critical resource, however, for many otherwise terrestrial species, which use wetlands for feeding and cover, such as moose (*Alces alces*), raccoon (*Procyon lotor*), and mink (*Mustela vison*).

Animal communities of saltwater wetlands can differ substantially from those in freshwater systems because of the effects of salinity on animal metabolism. Generally speaking, analogous taxa occur in freshwater and saltwater wetlands, such that similar niches are occupied, but species richness of animals generally declines along a freshwater-brackish-saltwater gradient. Reptiles from the Gulf of Mexico region provide an example: about 24 species occur in fresh marsh, 16 in brackish marshes, but just 4 in salt marshes. Of the salt marsh species, few are salt marsh specialists. Some terrapins are largely restricted to salt marsh habitats, but other regularly encountered salt marsh inhabitants, such as cooters and alligators, actually prefer freshwater situations. Amphibians show a particularly sharp trend along the wetland salinity gradient. Owing to their highly permeable skins and inability to counteract the drying conditions produced by high osmotic pressures of salt water, very few species can survive in saline wetlands and even then occur only infrequently (e.g., some toads).

Relatively few breeding birds specialize on salt marsh habitats, although sparrows and rails are well represented. However, salt marshes are noted for their importance as stopover sites for the vast populations of migrating species that breed in freshwater wetlands that freeze in winter. Waterfowl, shorebirds, songbirds, and owls can occur in brackish and salt marsh habitats in large numbers during the colder months resulting in very diverse, if unstable, assemblages during the winter period. Thus, though occupied for relatively short periods, and not by a large number of breeding species, coastal marshes nevertheless are a critical habitat in the annual cycle of many bird species.

Mammal communities in saltwater wetlands are generally quite species poor. However, the occasional effects of high densities of aquatic rodents (e.g., muskrats and nutria) can

be of ecological significance. As in freshwater systems, these species can radically alter the wetland environment through so-called “eat-outs” of the vegetation. Otherwise, saline wetlands are infrequently visited by species more dependent on freshwater wetlands, such as otter, mink, or raccoon.

Overlap of freshwater and marine species, in conjunction with resident species that can tolerate the substantial fluctuations in salinity, produces highly complex, species-rich assemblages of fish and crustacean species in saltwater wetlands. Though characteristically species rich, these assemblages are temporally quite unstable because of daily tidal cycles, with freshwater-associated species descending into salt marsh systems on outgoing tides and marine species arriving on incoming tides. In particular, many marine fishes and crustaceans, especially shrimp, use salt marshes as nursery areas, particularly for post-larval and juvenile forms. Here they take advantage of the lower numbers of predators in salt marshes relative to the open ocean and have access to the high productivity of salt marshes.

Controls of Species Diversity

Within particular wetland ecosystems, plant and animal diversity reflects the interacting influence of a number of abiotic and biotic variables that operate across a range of spatial and temporal scales. Diversity in wetlands cannot be understood without attention to these gradients, the scales at which they operate, and their interactions. Of the physical and chemical variables, hydrologic regime, mineral ion concentrations, pH, nutrient availability, salinity, and disturbance have been shown to play particularly strong roles. They largely determine the number of species that are physiologically capable of living in a site. Important biotic variables include primary productivity and interspecific competition. Along with abiotic factors, they influence which plant and animal species actually occur within the site. Because the composition, structure, and density of vegetation form key elements of habitat for animal species, these gradients also strongly influence animal diversity.

Depending on the type of wetland, different abiotic and biotic variables assume greater or lesser importance in determining species distributions. Hydrologic regime is important in all wetlands for both plant and animal species. Saturation with water severely restricts diffusion of oxygen into the soil while microbes rapidly deplete available soil oxygen. Hydrologic regime, therefore, largely determines the distribution and frequency of the most universal stress to which wetland plants and animals must adapt—anoxia in the water column, shallow soils, and rooting zone of plants. Salinity generally assumes importance only in coastal wetlands and in the saline wetlands of semiarid and arid regions. However, inland salt marshes occur in the Great Lakes region and some of the wetlands of the prairie pothole region of North America are saline. Mineral ion concentrations and pH affect species composition in all types of wetlands but have particular significance in peatlands that exhibit both extremes of the gradient in these factors. The combination of low nutrient availability, low pH, and low concentrations of calcium and magnesium makes bogs inhospitable environments for most

plant and animal species. The extremely high pH and calcium concentrations of some rich fens are associated with high species richness and a large number of rare and uncommon species of plants and snails. Nutrient availability, which is lower in all undisturbed peatlands than in mineral soil wetlands, has become an issue for many types of wetlands as humans have increased nutrient inputs to wetlands.

Flowing water, especially at faster rates and larger volumes, exerts an additional mechanical stress on wetland species in some environments. Plants growing in river floodplains, tidal marshes, and other wetlands subject to flooding with rapidly flowing water must be able to withstand the force of moving water or must have life histories that allow them to germinate and reproduce in periods between floods. Well-developed root systems and flexible stems are essential for perennial plant species. Animals in these environments must be able to move out of the reach of flood waters, either into sediments or the tops of trees or out of the flooded area.

Many types of disturbance—factors that remove plant biomass—affect wetland diversity. Extended periods of inundation with deep water kill most emergent plants, which allows new species to germinate when water levels drop. Muskrats and nutria eat marsh vegetation. Moose consume wetland shrubs and aquatic vegetation. Beavers fell trees, alter hydrologic regimes with their dams, and destroy existing vegetation in digging for mud to strengthen the dam. The flooding created by beaver ponds destroys flood-intolerant vegetation. Tides and storm surges deposit patches of debris that bury vegetation in coastal wetlands. Hurricanes rip trees out of swamps and deposit sediment and other debris in wetlands. Humans harvest timber from swamps in many parts of the world. In Africa, southeastern Asia, and parts of South America, humans harvest other wetland plants for various uses, including firewood, food, and shelter. Reeds (*Phragmites communis*) are still harvested in The Netherlands and England as thatching for roofs.

Change over time as well as space is the rule in wetlands. Because climate drives hydrology, seasonal, annual, and longer-term changes occur in water depth and all the chemical and physical factors it regulates. Extended periods of wet or dry years dramatically change the distribution of both plant and animal species. Some wetlands systems, such as the prairie potholes of North America, have 10- to 20-year cycles of wet to dry climate. In other regional wetlands, such as the deep-water cypress swamps of the southeastern United States, wet to dry cycles occur over much longer time periods. The effect of this temporal variation at many scales is to increase overall species diversity by promoting a dynamic community composition and spatial distribution among years. In wetlands where organic matter accumulates as peat, even more dramatic changes occur with time; the landscape itself is transformed. Over hundreds to thousands of years, a mineral-rich, deep-water pond with high pH and relatively high nutrient availability can change to a raised bog with low pH, low nutrient availability, and low mineral ion concentrations (Figure 6). The plants and animals of a pond are replaced with those of the bog. Long-term deposition of mineral sediments in estuaries can create similarly dramatic changes in topography, landform, and the hydrologic regime for wetland organisms.

Figure 6 Raised bog, coastal Maine, USA.

Controls of Plant Species Richness

The question of what controls patterns in plant species richness is an old one that has received renewed attention with observed declines in species diversity over much of the globe. In wetlands, the question has been resolved only in part. The effects of many single factors are relatively well understood because of the over-riding importance of some physical and chemical variables in determining the pool of species physiologically capable of living in a site. Spatial and temporal heterogeneity, long recognized as critical determinants of species richness in other systems, are also positively correlated with species richness in wetlands. However, the relative importance of interacting sets of variables, operating in different types of wetlands and over different spatial and temporal scales, is only beginning to be understood. Because humans have increased nutrient inputs to many wetlands, the question of the relationship of plant species richness to nutrient availability, community productivity or biomass, and competition continues to motivate many wetland studies. Controls operating at regional and global scales have been little studied.

Gradients in several physical and chemical factors show strong correlation with species richness in wetlands, especially at the ends of the gradients where stress on plant growth is high. While more than 6700 species, approximately one-third of the total United States vascular flora, grow in wetlands, few species have evolved to persist in wetlands with low pH, high salinity, continuous inundation with shallow water, or high flooding frequency. Hence, bogs (low pH), the low marsh zone of salt marshes (high salinity), deep-water marshes (continuous inundation), and wetlands in the active channels of rivers (high flooding frequency) are all species-poor. In general, species richness increases with decreasing stress due to abiotic factors.

Numerous studies have shown that water level fluctuations are critical to maintaining species diversity in a wide variety of wetlands. Alternating periods of inundation and exposure of the soil create temporal and spatial gradients of water depth that provide conditions for germination of the largest number of species. Species diversity always declines when water levels are artificially stabilized. Several studies have shown that coastal plain ponds, Great Lakes shoreline vegetation, prairie wetlands, and Carolina bay wetlands all require fluctuations in water depth to maintain overall species richness.

Spatial heterogeneity increases the number of species co-occurrences in wetlands through a number of mechanisms. The presence of hummocks and hollows in peatlands creates small-scale gradients in pH and moisture that allow species with a wider range of tolerances to coexist in relatively small areas. The presence of mounds and tree bases in floodplain swamps provides sites for germination of a number of species that do not germinate or persist in standing water. Old muskrat mounds serve the same function in cattail marshes. Microtopographic variation in riparian wetlands causes spatial variation in flood frequencies that results in higher species richness. Deposition of wrack (dead plant debris) by tides and storms increases species richness in salt marshes by producing openings in dense stands of *Spartina*; these openings have higher salinity than the surrounding vegetation and are colonized by more salt-tolerant species (e.g., *Distichlis spicata*). High variation in substrate pH, type, texture, and age creates microhabitat variation along arctic, boreal, and tropical rivers and increases the number of plant species occurring in riparian vegetation.

Some of the spatial heterogeneity associated with higher species richness in wetlands results from various types of disturbance. In general, richness first increases and then decreases along gradients of increasing disturbance so that richness is highest at intermediate points along the gradient. In many environments, lack of disturbance allows a few highly competitive species to displace other species through the process of competitive exclusion. Disturbance disrupts this process and allows other species to persist. However, richness decreases if disturbance is too frequent because few species are adapted to very high disturbance frequencies.

Fertility, or nutrient availability, appears to be another strong control on plant species richness. However, few studies have actually measured nutrient availability because of the difficulty of doing so. Rather, nutrient availability has been inferred from surrogates such as community biomass, percent soil organic matter, or substrate texture. Use of these surrogates generally suggests that species richness is highest at moderate levels of community biomass and presumably, therefore, at moderate levels of nutrient availability. Close inspection of the data shows that richness can be low or high at low to intermediate levels of community biomass but almost always decreases above some threshold of high biomass. The amount of biomass at which that threshold occurs, however, varies greatly among wetland types. Furthermore, the relationship between richness and biomass appears to be scale-dependent. When data from wetlands with different vegetation types are examined, richness follows a unimodal relationship with community biomass. Within small plots within types, the relationship breaks down.

The complex interplay of abiotic factors with biological variables such as competition and productivity has been examined in only a few freshwater wetlands and seldom through experimental manipulation of variables. Salt marshes have received more attention. Results from these studies emphasize that the relative importance and direction of the effect of biotic variables on species richness change along gradients of stress. Abiotic variables play the strongest role where stress is high but the presence of some species can ameliorate the stress for other species (e.g., by lowering salinity through shading,

which decreases concentration of salts due to evapotranspiration). Species richness is thereby increased above what abiotic conditions might otherwise allow through positive interactions among species. Nonetheless, the number of species tends to decline monotonically with increasing stress from abiotic factors. Where stress is minimal, biotic control of species richness is greater. Here, variables related to density effects (e.g., productivity, biomass, light) are more likely to control variation in species richness, probably through competitive effects of dominant species on subordinate ones. In such environmentally benign wetlands, productivity is likely to be high and a few species are likely to dominate unless the process of competitive displacement is disrupted by disturbances that remove plant biomass and allow other species to establish.

The interplay of these local biotic and abiotic factors is played out against the background of regional and historical controls on the species pool (i.e., the number of species available to colonize a site). While local and current conditions determine which plant species do colonize a site, the regional species pool sets the upper limit to the number of species that could colonize the site. The geological, evolutionary, and ecological history of a region, along with its area, controls this pool. Geological age, processes of speciation and extinction, geographic dispersal, and chance historical events all leave their imprint on the species pools of particular regions. Few attempts have been made to relate the species pool to the number of species actually co-occurring in a site because of the difficulty of obtaining adequate data sets.

Controls of Animal Species Diversity

Patterns of diversity and productivity in wetland animals follow gradients strongly related to hydrologic regime, primarily because of its effects on the composition, structure, and productivity of wetland vegetation and on oxygen availability within the water column and wetland sediments. Oxygen levels most influence the distributions of wholly aquatic, nonmigratory wetland animals (i.e., the macroinvertebrates and fishes). The productivity and diversity of wetland invertebrates and fish, and, consequently, many water birds and mammals, are highest in semipermanent wetlands (e.g., those flooded during most of the growing season but dry otherwise). Most amphibians, however, occur in transient pools. Trends in reptile diversity and productivity along this inundation gradient are not clear.

Semipermanent and permanent water bodies are the primary habitats of fish, which generally lack the ability of many other wetland inhabitants to disperse overland or enter dormancy when wetlands dry. Thus, areas of sufficiently oxygenated water must occur in wetlands throughout the year to support fish populations, especially those of large-bodied species. Large, seasonally flooded wetlands with pools or channels that remain permanently flooded, and lakes with well-developed littoral vegetation tend to support the most diverse fish communities. Similarly, fish-eating birds and mammals frequent the habitats occupied by their fish prey. In contrast, temporary, unvegetated pools are the primary breeding habitats of amphibians, offering two main advantages. First, amphibian larvae are able to exploit a pulse of primary productivity that occurs shortly after pools fill with

water. Second, temporary pools will not support fish, major predators on amphibian eggs and larvae.

Many other wetland animals exploit intermittently flooded wetlands. Waterfowl, particularly egg-laying females, frequently travel among shallow pools, ditches, and puddles to feed on the pulse of invertebrate production that occurs following flooding. These feeding pools often are remote from nesting areas at more permanent wetlands, where deep waters and dense vegetation protect nesting birds and their eggs from predators. Similarly, snakes and turtles often can be found in temporarily flooded wetlands, and seek refuge from subsequent low-water periods by migrating or entering dormancy in a wetland's sediments.

Much of the variation in cover and food for wetland fauna, and hence in animal diversity, is associated with variation in the species diversity, density, and structural characteristics of wetland plants. Many wetland animals show affinities for particular life-forms of hydrophytes (e.g., submerged plants, floating-leaved plants, or emergents), and some are associated with specific plant taxa. For example, most aquatic invertebrates seek protection from predation and safe oviposition sites in macrophytes. In general, plants with dissected leaves support more invertebrates than plants with broad leaves. Macroinvertebrate diversity and density generally are greater in vegetated than open water areas, and, within vegetated areas, are greatest in areas of mixed emergent and submerged vegetation. Shading by erect hydrophytes also influences macroinvertebrate abundance; unshaded areas of submerged vegetation often support dense populations owing, in part, to elevated water temperatures in unshaded areas. Similarly, shallow, vegetated wetland habitats fringing deep-water areas are critical nursery habitats for fishes, many species of which use stands of particular wetland plant species as spawning habitat. These areas provide protective cover for eggs and larval fishes and food resources for young fishes. Like aquatic insects, many fishes prefer unshaded, shallow areas where warm water temperatures hasten the development of eggs and larvae.

Two key water chemistry parameters that influence distributions and diversity of wetland animals are acidity and salinity. The relationship of acidity to the distribution of wetland animals can be complex. For example, many aquatic, fish-eating birds frequent wetlands with moderately acidic waters (pH 5.5–6.0). Although fish populations often are reduced in wetlands with waters of pH < 6.0, suspended material may precipitate from the water column at low pH. The resulting increase in water transparency may improve encounter rates with prey and capture success for birds that pursue their prey underwater, and thereby compensate for decreased fish density. The reduction or loss of fish from moderately and strongly acidified waters also reduces competition between fish and insectivorous birds for macroinvertebrate prey. This may explain why dabbling ducks frequent waters of relatively high acidity that fish-eating ducks avoid. Highly acidic waters (i.e., pH < 5.0) generally support few fish or amphibians and have low diversity of aquatic invertebrates. Water bird and mammal use of such wetlands is limited.

Salinity strongly limits animal diversity in wetlands, primarily through effects on the composition of plant and invertebrate communities and through its direct physiological

effects on wetland animals. Difficulty in maintaining water balance leads many dabbling ducks, particularly those brooding young, to avoid wetlands with highly saline waters. Owing to their highly permeable skin, amphibians are intolerant of even moderately saline conditions. For similar reasons, highly saline conditions often limit the survival and hatching success of fish eggs and survival of larval fish. Many mammals, such as muskrats, are tolerant of highly saline conditions, but populations often are limited by the low quality of forage plants that grow in saline wetlands.

Three spatial characteristics of wetlands and their distribution in the landscape—size, connectivity, and isolation—also influence the diversity of wetland animals within and among sites. For example, small wetlands often support fewer species of birds than large wetlands, and isolated wetlands support fewer species than wetlands in complexes. Aquatic, fish-eating birds are particularly sensitive to wetland area and often shun small wetlands (<10 ha). Small wetlands may not provide a sufficient quantity of habitat or prey for many large-bodied species, and short inter-wetland distances may provide certain species with alternate foraging sites while minimizing their time in flight. Larger wetlands generally support a wider diversity of vegetative life-forms and, therefore, may provide a greater variety of habitats for wetland species than smaller wetlands. This may account for the frequently observed pattern of increased fish species diversity in larger than smaller wetlands.

The proximity of diverse habitat types within a wetland, and connectivity among wetland environments and with upland habitats, is critical to maintaining high diversity of wetland animals, particularly amphibians, some birds, and fish. Aquatic breeding and terrestrial nonbreeding habitats must be contiguous for amphibian populations to persist. Local breeding populations undergo frequent extinction and recolonization events, and individuals often are exchanged among populations. The importance of migration in amphibian population ecology is indicated by the presence in many species of a juvenile stage adapted strictly for dispersal. Destruction of larval or adult habitats, or the connections between them (e.g., riparian corridors) often drives local amphibian populations to extinction.

Proximity of diverse habitat types within a wetland is critical to many breeding water birds and fish. Some water birds, such as rails, dwell within dense stands of emergent vegetation, while others, such as bitterns, herons, and shorebirds, forage mainly along the interface of wetland vegetation and open water. Still others, such as grebes and many dabbling ducks, are associated with floating and submerged vegetation, while loons and cormorants forage in deep, open waters. Most of these birds, however, build their nests within dense stands of emergents, on small islands, or in trees or shrubs.

Fish assemblages provide another example of the importance to wetland animals of spatial heterogeneity and connectivity in wetland habitats. Most large species of bottom-feeding and predatory species undergo small-scale migrations between feeding and spawning areas in shallow wetlands and resting areas in deeper, open-water habitats. These migrations often occur nightly, with fishes returning to deep waters to rest during the day. Critical to these migratory movements are the links established between shallow, vegetated areas and deep-

water zones by seasonal regimes of wetland flooding. Finally, many fishes undergo seasonal migrations over hundreds of kilometers into river floodplains and return to the river channels as waters recede.

Some wetland animals create some of the spatial and temporal heterogeneity that promotes animal diversity in wetlands. Beavers alter stream channels and transform riparian forests into freshwater marshes and ponds with stands of dead timber. Beaver activities also permanently modify soils beneath dam sites and even change local topographies; beaver dams reduce current velocities and cause massive silt depositions, which remain long after the dams disintegrate. High levels of herbivory by muskrats and geese can result in “eat outs,” whereby essentially all emergent plant material in a marsh is consumed over a few years. Such drastic, animal-caused modification of the wetland environment not only affects habitat availability for other wetland animals but can alter patterns of energy flow and biotic productivity within wetland ecosystems. Other, less drastic examples of habitat modification include the activities of alligators, which construct small basins that serve as critical refuges for many fishes, and important feeding areas for fish-eating birds, during low water periods (Figure 8). Crayfish burrows serve in many areas as moist refuges for water snakes, salamanders, and frogs.

Functional Diversity

Wetland plants exhibit a diverse array of adaptations that allow many species to tolerate stresses associated with soil saturation, alternating periods of flooding and drought, high salinity, low pH, and low nutrient availability. Other adaptations assist wetland plants in dispersal and establishment. Animals also exhibit an array of adaptations to wetland environments, although unlike plants, many simply can move to escape stresses. Collectively, these adaptations explain much of the high species richness and diversity of many wetlands, especially those with strong hydrological and chemical gradients.

Adaptations to Anoxic Environments

Many wetland plants have one or more morphological and anatomical adaptations that allow them to tolerate soil saturation and anoxia for short to long time periods, primarily by allowing more oxygen to reach the plant root system. Key morphological adaptations include (a) aerenchyma, air spaces in roots and stems that allow oxygen diffusion from stems above water to roots; (b) hypertrophied lenticels, enlarged openings in stems and roots that allow gas exchange between internal plant tissue and the atmosphere; (c) adventitious or stem roots developed above the water line; and (d) the ability to grow new roots under anoxic conditions. In black mangrove (*Avicennia*), pneumatophores, vertically growing air roots, absorb oxygen that is transported to the connected, submerged, lateral growing roots. Prop roots of red mangrove (*Rhizophora*) function in much the same way. In both mangrove species, oxygen enters the plant through lenticels exposed above water and diffuses to roots in anoxic sediments.

Many woody species of alluvial floodplains have extensive, shallow root systems placed where sediments are least likely to experience oxygen deficits.

Plant physiological adaptations generally involve tolerance to low soil oxygen and specialized chemical reactions. Specialized reactions include an accumulation of malate instead of ethanol, the production of high levels of nitrate reductase, and a reduction in ethanol production by reducing alcohol dehydrogenase activity. Additionally, rhizosphere oxygenation is an important mechanism for many species and can lessen toxic concentrations of some anaerobic soil compounds.

Wetland animals, with their characteristically high metabolic rates, have developed a variety of adaptations to low levels of oxygen and carbon dioxide. Perhaps most obvious is development of specialized regions of the body for gas exchange. Examples include gills in fish and crustacea, parapodia in polychaetes, and highly vascularized tissues on the lower lips of some tropical fishes or in the cloacas (urogenital openings) of turtles. Other physical adaptations include modification of respiratory pigments to improve oxygen-carrying capacity in invertebrates. For example, midge larvae (*Chironomus*) are often colored brightly red, indicating the unusually high concentrations of hemoglobin present in these organisms, permitting them to survive long periods of hypoxia. Some vertebrates, particularly fishes, also increase densities of circulating red blood cells and thereby their oxygen-holding capacity.

Physiological adaptations of animals primarily involve shifts in metabolic pathways. For example, bivalves use alternative biochemical pathways, primarily a switch to glycolytic fermentation, to increase energy production under anoxic conditions. Some invertebrates also diversify the by-products of glycolysis to avoid toxic accumulation of any single compound, particularly ethanol. Turtles are remarkable for the ability of these lung-breathers to remain under water submerged in sediments for months during the winter season. Biochemical adaptation for natural anoxia tolerance in turtles includes well-developed antioxidant defenses that minimize or prevent damage by reactive oxygen species during the reoxygenation of organs after anoxic submergence. Last, many invertebrates store large quantities of respirable carbohydrate, usually glycogen, for breakdown and oxygen-liberation during periods of anoxia.

Behavioral adaptations also are critical and widespread, including dormancy or low locomotor activity during periods of oxygen stress, and migration from hypoxic to oxygen-rich environments. Many animals in low-oxygen situations have developed means of moving water more rapidly across respiratory surfaces. For example, benthic animals often use a variety of behavioral means (fanning, retreating into and out of burrows) to ventilate their burrows and increase the water flow across membranes during times of hypoxia.

These adaptations combine in interesting ways in particular taxa. Some fishes highly adapted to mud and shallow-water swamps cope by aestivating in mucous cocoons or by migrating overland while air breathing through modified swim bladders (e.g., lungfish). Some aquatic microinvertebrates, such as Collembola (spring-tails) and mites (Acari), have developed a "physical gill" that traps air gathered at the water surface in body surface hairs. Breathing of the trapped air,

while underwater, occurs via a tracheal system, which opens to the body surface. Some aquatic insects, including mosquito larvae and chrysomelid beetles, tap the air within the aerenchyma of plant roots using a highly specialized, spinelike siphon attached to their abdomens. Last, some fly larvae use snorkel-like devices that extend above the surface of liquid mud or anoxic water and that permit the animal to air-breathe while remaining submerged in the anoxic substrate.

Adaptations to Salinity and Drought

Although halophytes (i.e., plants capable of persisting in saline environments) are not restricted to wetlands, these species dominate saline wetlands, such as inland and coastal salt marshes, and coastal fringe forests. Some species, such as various mangroves (*Avicennia*, *Laguncularia*, and *Rhizophora* spp.), are facultative halophytes and have mechanisms to inhibit salt absorption by their roots and to excrete salt from their leaves. Because nonhalophytes ("glycophytes") exhibit a range of tolerance to a salinity gradient, salinity and flooding regime determine plant species composition and richness along a gradient from salt marsh to tidal freshwater marsh. Plant species that use the C_4 pathway of photosynthesis are well adapted to habitats subjected to drought stress. Saline wetlands, therefore, often are dominated by C_4 plant species because the salt content makes water uptake more difficult. Plant species with C_4 photosynthesis are much more efficient in fixing carbon and in water use and have higher rates of net photosynthesis, growth, and dry matter production than C_3 plants.

Little is known about adaptations of wetland animals to salt stress. The fundamental problem of salt stress is its effect on water movement at the cellular level, which interferes with metabolic processes. Most simple microinvertebrates are osmoconformers whose internal salt concentration tracks that of the external environment. More complex wetland animals, particularly vertebrates, typically osmoregulate—that is, retain internal salt concentrations independent of those external to the body. Osmoregulation primarily involves moving ions across body membranes against the concentration gradient and is thus an energy intensive process. This process is usually associated with specialized renal organs (kidneys and antennal glands) and salt-secreting nasal or rectal glands. Behavioral adaptations, particularly short-term migrations, are common in mobile species. In such a manner, both freshwater and marine species can occur in salt marshes, retreating during unfavorable periods either upstream (freshwater species) or downstream (marine species) during the course of the daily tidal cycle.

Adaptations to Low Nutrient Availability and High Acidity

Nitrogen fixation is relatively uncommon in wetland vascular plants but the few examples are noteworthy. Nitrogen fixation by sweet gale (*Myrica gale*) can contribute 3 to 4 g N m⁻² yr⁻¹ to *Sphagnum* bogs. Nitrogen fixation rates of speckled alder (*Alnus rugosa* = *A. incana* ssp. *rugosa*) have been measured at 85 to 167 kg N₂ ha⁻¹ yr⁻¹. Some nonsymbiotic, aerobic and anaerobic bacteria, and blue-green algae are also significant nitrogen fixers in wetlands (Figure 7).

Figure 7 Acidic peatland, coastal Maine, USA.

Most of the carnivorous species in the world occur in wetlands and other oligotrophic habitats. The relationships between insect capture, mineral nutrition (particularly nitrogen and phosphorus), and plant growth and reproduction have been investigated for numerous species. The relatively large diversity of organisms that can survive in the “pitchers” of some carnivorous plants also has been studied (**Figure 9**). Although benefits to carnivorous plants have been demonstrated, there is limited evidence that carnivory is necessary for most species to survive.

Evergreen, sclerophyllous shrubs that generally belong to the Ericaceae (heath family) are characteristic of nutrient-poor peatlands. The role of this foliage type in wetlands is uncertain, but it has been suggested that plant species with evergreen leaves may be more efficient in using nutrients than species with deciduous leaves. These leaves, which persist for up to four years, extend the period that the plant can photosynthesize, which conserves energy in the plant because all of the leaves do not have to be renewed each year. Furthermore, evergreen species tend to resorb more nutrients from senescing leaves than other species, thus increasing nutrient use efficiency. High nutrient resorption and long retention of nutrients in evergreen sclerophyllous leaves may be especially important in phosphorus-poor habitats such as bogs.

One of the most important groups of plants in colder, generally acidic wetlands of the world are *Sphagnum* mosses, a

Figure 8 Alligator in pool at Everglades National Park, southern Florida, USA.

Figure 9 Yellow pitcher plants in pocosin, South Carolina, USA.

Figure 10 Acidic peatland in the Adirondacks, New York, USA.

large genus consisting of more than 135 species (**Figure 10**). These mosses can thrive in conditions highly stressful to most plants (e.g., low pH, low nutrient availability, and saturated soils). They are the primary peat producers worldwide and have the capacity to modify the environment in ways that favor their own growth. Once established, *Sphagnum* mosses can further acidify their environment through cation exchange processes and by excretion of polygalacturonic acids. They

also paludify their environment through their high water-holding capacity and their role in peat accumulation which can block water drainages. *Sphagnum* species also can tolerate great desiccation. Three major gradients exert the greatest influence on the bryophyte flora of peatlands: acidity–alkalinity, dry–wet, low light–high light. Numerous *Sphagnum* species can occur even within a relatively small peatland because of the affinities of particular species to very specific pHs, other water chemistry variables, height above water table, and light.

Adaptations to Reproducing in Wetlands

Seeds of many wetland species have features that enable their dispersal by water (hydrochory). Red mangrove (*Rhizophora mangle*) produces seeds that germinate while on the parent tree, resulting in viviparous seedlings. The germinated seed can root if it lands on sediment. Otherwise, the seedling floats until a suitable substrate is reached.

Seed banks, the store of seeds that accumulate in soils, play a critical role in the long-term vegetation dynamics of many types of wetlands worldwide. Seed banks allow wetland vegetation to adjust to rising and falling water levels and help maintain compositional diversity across water depth gradients and from year to year and over longer climatic cycles. Most wetland species do not germinate under water and only a few survive more than a year or two of continuously deep water. A series of wet years can eliminate most vegetation, but when water levels fall, many species that existed only as seeds in the seed bank germinate in the wet exposed mud. Thus, fluctuating water levels and seed banks drive wetland succession. Seed banks are particularly important in maintaining the species composition and zonation of wetlands that have a large number of annual species (e.g., tidal freshwater marshes). An understanding of the seed bank is essential in wetland management, especially in restoration efforts.

Seed density in wetland soils, usually determined by germination tests, typically ranges from 1000 to 14,000 seeds m^{-2} with density and viability decreasing with increasing depth in the substrate. Graminoids (grasses and sedges) are often the most abundant group in wetland seed banks, with seeds of broad-leaved herbaceous and woody species far less abundant. Although the composition of the seed bank and plant species present in the wetland can be highly correlated, in many cases the seed bank harbors a much greater species richness than found in the extant vegetation. Seeds of some species are transient, while others can persist for decades.

The greatly enlarged, rounded bases of water tupelo (*Nyssa aquatica*) (Figure 11) and buttressed bases of bald- and pond cypress (*Taxodium spp.*) develop especially in deeply flooded conditions. These swollen bases likely aid in anchoring the tree. The “knees” of *Taxodium* also may function in this manner. *Taxodium* buttresses appear to provide a refugium above water for numerous species of herbaceous and woody plants that become established in the crevices where organic materials have accumulated over time. In some deep-water swamps, alternative colonization sites are limited for many plant species.

Figure 11 Water tupelo in southern deepwater swamp, South Carolina, USA.

Threats to Wetland Diversity

Worldwide, the loss of wetlands is estimated at about 50%. Functionally, the losses are much greater because extensive areas of boreal wetlands have been little altered while many different types of regional wetlands have been reduced by 80 to 90% elsewhere (e.g., California, southern Ontario, southwestern France, New Zealand). Wetland diversity and numerous plant and animal species have been impacted by a host of anthropogenic activities and natural disturbances for centuries. While single and cumulative effects of these activities have been assessed for many wetland species (primarily wildlife) and functions, few studies have examined the effects of these activities on species diversity. Because human activities often modify wetland hydrology and water chemistry, one should expect significant changes in diversity given the well-established relationships between wetland hydrology, water chemistry, and species distributions.

Despite the relatively recent appreciation of wetland functions and values, wetlands continue to be destroyed. A notable example is the Pantanal of Brazil, the world's largest wetland and home to many endangered or threatened plant and animal species. Various development plans, including

Figure 12 Freshwater marsh in the Adirondacks, New York, USA.

dam and highway construction, threaten the diversity of this vast wetland. Although some human activities may be able to be carried out in a sustainable manner in wetland habitats, habitat preservation is the key to preserving wetland diversity around the world.

Direct Habitat Destruction

By far, the majority of palustrine wetland loss in North America has been due to agricultural activities, especially direct conversion of wetlands to agricultural land. Agricultural uses have converted over 80% of the Mississippi River bottomland hardwood forest. About 90% of the wetlands in California, Ohio, and Iowa have been destroyed, primarily for agriculture. Wetlands adjacent to agricultural lands also can be adversely affected because drainage effects can extend a significant distance into the wetland. Coastal wetlands, most first altered by agricultural activities, including grazing and salt production, are now impacted by draining and filling for urban and industrial development. Drainage of wetlands on organic substrates leads to accelerated decomposition, erosion of organic matter, and release of carbon dioxide (a “greenhouse” gas) into the atmosphere.

Riparian wetlands in the western United States can be seriously degraded by cattle grazing, which adversely affects

the adjacent aquatic ecosystem. Wildlife species composition and diversity are modified because heavy grazing reduces the structural complexity of riparian wetlands.

Timber harvest, when done without extensive drainage and total land clearing, generally converts forested wetland to earlier successional stages, or changes species composition and structure. Logging, specifically the extraction of cut trees through mechanical skidding and transport of heavy log loads, adversely modifies soil physical properties. Early logging of southern forested wetlands was typically done with no regard for sustainability. Consequently, forest composition and structure were dramatically altered. Logging roads can modify wetland hydroperiods such that productivity is raised or lowered. Occasionally, especially in northern forested wetlands, a heavy timber harvest can raise the water table, flooding already established species and decreasing the regeneration sites for new plants. Whole-tree timber harvest of oligotrophic peatlands can greatly reduce a site’s nutrient pool.

Tropical intertidal zones are being increasingly altered for mariculture, especially mangrove wetlands for shrimp farming. Many salt marshes have been ditched and diked, and often converted to impoundments, to favor waterfowl.

Peat extraction, primarily for fuel or horticultural uses, has destroyed millions of hectares of peatlands in North America, Great Britain, and northern Eurasia. Where the mined peatlands have been abandoned or actively managed for conservation values, the vegetation can slowly recover. Which species come to occupy the site depends on the hydrology of the site, availability of propagules, and time since abandonment.

Gravel and sand mining can adversely affect wetlands directly by habitat destruction, and indirectly by changing the hydrology and water chemistry of an adjacent wetland. These mining activities can be especially damaging to ombrotrophic and minerotrophic peatlands (e.g., bogs and fens) because many of the characteristic species occur at very specific water levels and chemistry parameters.

Direct Alteration of Wetland Hydrology

Humans alter wetland hydrology primarily by building dams at wetland outlets to regulate the depth and duration of inundation, and by constructing channels and ditches to drain wetlands and prevent prolonged flooding. Artificially regulated water levels often result in impoverished animal communities because few species of wetland animals have life histories adapted to the stable water regimes that result. This decrease in diversity occurs even where water control structures were originally built with the intention of benefiting wetland animals (e.g., at wildlife refuges). Management strategies for many water impoundments now seek to emulate the “natural” flooding regimes that were present before impoundments were built. Wetland drainage has obvious and drastic effects on wetland animal communities and has resulted in a loss of about half of the original habitat available to the wetland fauna of the United States. Among the most imperiled wetland habitats are the easily drained, intermittently flooded basins and pools that are critical to a large proportion of the wetland fauna.

Dam construction and water diversion projects also have significant effects on downstream riparian vegetation by altering peak and minimum flows, decreasing erosion and deposition of sediment, and lowering floodplain water tables. Altering the natural variability of river flow can adversely affect the species composition and structure of riparian wetland vegetation. Dredging, channelization, and levee construction have greatly impacted extensive wetland areas in the Mississippi River Delta.

Groundwater extraction is a primary cause of wetland modification because it lowers the regional water table and alters recharge and discharge patterns within the wetland and surrounding landscape. Irrigation with water supplied by aquifers that are recharged in part by wetlands has led to declines in the area of major regional wetlands in North America (e.g., the prairie pothole and Nebraska sandhills regions).

Although plant species of coastal wetlands may be well adapted to flooding, increases in the level or duration of flooding above that at which species have long persisted can cause serious deterioration of these wetlands. Sea-level rise and saltwater intrusion are important factors in the degradation and loss of wetland forests and coastal marshes in the southeastern United States. Increased flooding and salinity have been particularly damaging to forests dominated by baldcypress.

Landscape Fragmentation

Other human activities impoverish the wetland fauna in more subtle ways, even where wetlands receive nominal legal protection. Destruction of the uplands adjacent to wetlands destroys the habitat interface critical for amphibians and reptiles that migrate between wetland and upland habitats. Reductions in the connectivity among wetlands (e.g., by construction of roads and levees) blocks the migration routes of amphibians, fish, and birds, and can lead to local population extinctions. In contrast, dredging of canals that link major river systems causes sudden mixing of fish and reptile faunas that may have evolved in isolation for thousands of years.

Other Threats

Anthropogenic inputs of nutrients and toxins drastically alter the chemical environment of wetlands and render many sites unsuitable for wetland plants and animals. Atmospheric deposition of nitrogen and sulfur is particularly high in parts of western Europe but is also high in the northeastern United States. Atmospheric deposition may be especially damaging to peatlands dominated by bryophytes (mosses and lichens), because these species are very sensitive to changes in nutrients and acidity-alkalinity. Wetlands in agricultural landscapes receive excess nitrogen via ground water draining from agricultural fields and excess phosphorus primarily via surface water runoff. Residential development also contributes excess nitrogen and phosphorus to wetlands. Coastal oil spills can adversely affect the vegetation of salt marshes and tidal freshwater wetlands.

Invasive, exotic wetland species typically cause a substantial loss of native wetland species and greatly alter wildlife habitat. In otherwise arid regions, invasive species use substantial

amounts of water and can desiccate watercourses. Invasive species generally respond favorably to altered hydrologic regimes, substrate disturbance, or changes in water quality, especially eutrophication. Introduction of exotic wetland animals, for example, carp, nutria (*Myocaster coypu*), and bullfrogs, outside their native range have greatly altered wetland environments throughout much of North America, mostly to the detriment of the native wetland fauna.

Purple loosestrife (*Lythrum salicaria*), an emergent, herbaceous species of Eurasian origin, has become a serious invasive species of open wetlands in eastern North America. A single individual of this species can produce an average of 2,700,000 seeds. Another very serious invasive species in wetlands of the eastern United States is the common reed (*Phragmites communis*), which can produce 200 to 300 culms m^{-2} in fresh and brackish wetlands through an extensive network of rhizomes. Recent biological control methods (i.e., leaf- and root-feeding beetles) appear promising for *L. salicaria*.

Salt cedars (*Tamarix* spp.) are rapid, arborescent invaders of riparian wetlands in the southwestern United States, especially downstream from dams where flooding is minimal. Another invasive tree species of riparian wetlands in the western United States is Russian-olive (*Elaeagnus angustifolia*). In southern Florida, the invasive tree, melaleuca (*Melaleuca quinquenervia*), has been aggressively colonizing shallow wetlands. Two other tree species that seriously threaten southern Florida wetlands are Australian pine (*Casuarina*) and Brazilian pepper (*Schinus terebinthifolius*). Glossy buckthorn (*Rhamnus frangula*) is becoming a serious problem in wetlands around the eastern Great Lakes basin.

Some native species become invasive following some hydrologic changes or an increase in nutrients and dominate wetlands previously occupied by other, more desirable species. Cattail is regarded as a threat to southern Florida marshes that have been dominated by sawgrass (*Cladium jamaicense*). The spread of cattail is believed due mostly to increased phosphorus input from agricultural lands and anthropogenic changes to the regional hydrology. Cattail is also considered a weed in many wetlands and aquatic habitats that are used for agriculture or to provide water resources (e.g., rice fields, irrigation canals, recreational lakes, and reservoirs). Mechanical (e.g., cutting, water level modification, fire, shading), chemical (selective versus nonselective herbicides), and biological control methods vary in their effectiveness, which varies widely among species. Maintaining water levels over 0.5 m is effective in controlling spread of cattail.

Natural Disturbances

Severe flooding, hurricanes, and fire are the major natural disturbances that greatly affect wetlands. Although wetland plant and animal communities are adapted to each of these disturbances, events of exceptional magnitude and duration, or that occur during unusual times of the year, can have profound effects. A serious concern following any of these severe events is the spread of invasive species.

During the 1993 flooding of the Mississippi River, submerged aquatic, emergent wetland, and floodplain species

were adversely affected by extreme sediment deposition, uprooting due to wave action, and probably increased inputs of agricultural chemicals. Recolonization of open spaces left by plant mortality can happen quickly by germination of local or upstream plant propagules.

Hurricanes especially affect the mangrove forests of the Gulf of Mexico and Caribbean, and the deep-water and alluvial swamps of the southern United States. These coastal forests, where many species have shallow root systems, are often subjected to the highest winds and succumb to windthrow. Trees that are especially resistant to windthrow (e.g., *Taxodium distichum*) may lose most of their crown but are able to reestablish a new canopy quickly by extensive sprouting along the bole. Seedling regeneration is generally higher after such disturbances because of increased light and microsite availability. Storm surges of saltwater occasionally cause greater damage than high winds to species intolerant of high salinity.

Forested wetlands on substantial peat deposits, such as the black spruce (*Picea mariana*) and tamarack (*Larix laricina*) swamps of the boreal forest and baldcypress swamps of the southeastern United States, have naturally burned during periods of extreme drought. In northern climates, fires can convert the forest to a more open peatland. In the southeastern swamps (e.g., Okefenokee Swamp), fires can convert forested wetlands to prairie-like, tree-less wetlands. Fire can favor the regeneration of some tree species, like *Chamaecyparis thyoides* (Atlantic white-cedar), which regenerate best under full sunlight conditions on saturated peat. In the Everglades of southern Florida, open sawgrass marshes naturally burned every 1 to 5 years, ignited by lightning strikes from May to October when water levels are highest and substrates are saturated. However, human-set fires are most common from November to May when soils can be dry enough to ignite. These fires, to which the vegetation is not well adapted, can cause substantial ecological damage.

Restoring and Maintaining Wetland Diversity

Because of extensive loss and degradation of wetlands throughout the world, and continuing loss and degradation in much of the world, maintaining wetland diversity will require a strategy that includes restoration. The ultimate goal in any specific wetland restoration project is to have a self-sustaining, functioning ecosystem. The following discussion focuses on techniques to achieve this goal. However, in terms of restoring wetland diversity, the goal must be a broader one—best addressed at the landscape, regional, and continental scale—to restore the structure, function, and self-sustaining properties of a wide diversity of wetland types. Without attention to restoration of the full complement of wetland types, wetland diversity cannot be restored at any but the smallest scales.

Restoring self-sustaining wetland ecosystems initially, and at later times, may require various engineering, horticultural, and wildlife management activities (National Research Council, 1992). The intensity of these activities depends on whether the site was initially an upland (thus requiring wetland “creation”), a wetland that has been drastically disturbed (e.g., through conversion to agricultural crop production), or disturbed to lesser degrees. In some cases, a

wetland may have reached a successional stage that does not support a species or group of species of concern, and manipulation is required to maintain these species. Nontidal emergent wetlands are generally easiest to restore. Long-term monitoring of site hydrology and vegetation is required to determine if and when project objectives are not being met.

Because wetlands serve many functions, and seldom can all functions be restored in a single site, restoration objectives must be clearly defined for every project. Restoring wetlands as habitat for rare and uncommon species, or for overall biological diversity, especially requires clear statements of objectives, as well as thorough knowledge of the ecology of the species of concern. Wetlands that could be correctly described as functioning wetlands have failed to attract the species for which they were restored. Consider the restoration of a bottomland hardwood forest. The restoration could be viewed as successful if a certain percentage of planted oak (*Quercus*) species and individuals were to become established after a given period of time. However, such a planting would be a failure in terms of restoring the diversity of neo-tropical migratory birds, which would fail to use the site because they require a more complex forest structure. In general, a higher overall plant and animal diversity is achieved by planting an array of fast- and slow-growing plant species, and where appropriate a mix of woody and herbaceous species tolerant of the range of hydrological and chemical conditions at a site.

The first step to restoring wetland plant composition, structure, and function is to ensure a range of hydrological conditions by implementing various techniques. Depending on the existing condition of the site and restoration goals, these techniques may include reestablishing stream flow or tidal fluctuations, restoring flood regimes, halting drainage, and reestablishing topography and microtopography. These conditions can be attained by excavating basins or channels, constructing dikes, grading an undulating topography, installing water control structures, plugging ditches, and removing drainage tile lines. If the site is to be used for the reintroduction of rare species, there are additional considerations, especially genetic, political, and legal issues.

Once a range of hydrological conditions is established, plant species best adapted to each specific hydrological condition can be selected. Many wetland restorations fail because the relatively few plant species selected grow poorly or die because conditions are too wet or dry for too long. If the goal of a particular restoration is to restore functions such as flood control or nutrient retention, then relatively few plant species need to be planted. If the goal of a project is to restore the natural heritage or educational values of a wetland, or to reestablish the compositional and structural complexity of highly diverse wetlands, then many plant species should be established.

Sources of native trees, shrubs, sedges, grasses, and herbaceous species include plant nurseries and other wetlands, especially those that are planned for future, permitted alteration. Seeds of many wetland species can be collected and grown for future transplanting or direct seeding. Some woody species can be established from stem cuttings. Many herbaceous species can be propagated from divisions off the parent. Spreading soil collected from a donor wetland, especially

those planned for future alteration, will provide the greatest diversity of plant and animal organisms. Numerous woody and herbaceous plant species can arise from transplanted soil, via whole plants, seeds, roots, rhizomes, and stolons. Including leaf litter, detritus, and, for forested wetlands, large amounts of coarse woody debris are beneficial.

Herbivores cause many wetland restoration projects to fail, directly (by feeding) and indirectly (by burrowing, by dam building). Invasive species, such as *Lythrum salicaria*, *Phragmites australis*, and *Tamarix* spp., also must be controlled if plant and animal diversity are desired.

Understanding the ecological factors that control the diversity of animals in wetlands is key to altering these factors to restore, enhance, or create wetlands for the benefit of wetland fauna. Because hydrology underpins so much of wetland ecology, manipulation of wetland hydrology through water-level regulation is the most common and cost-effective way to manage wetland habitats for wetland fauna. More specifically, water-control structures can be used to flood or drain wetlands and thereby alter plant communities and the habitats available for wildlife. By drawing down water levels, a germination phase can be produced, which can be followed by gradual reflooding once plant communities become established. Timing, duration, and degree of drawdown (for example, shallow, growing season drawdowns versus complete over-winter drawdowns) influence subsequent plant species composition and the types of wildlife later attracted. Several years of stable water levels of moderate depth following drawdown are often required to establish the submerged plant communities that are important to many wetland animals (invertebrates, ducks, fish). Manipulation of wetlands to produce early stages of plant succession can create a diversity of habitat niches for wetland animals, particularly if practiced within a wetland complex in which management of different units is staggered for different successional stages. This practice permits the wetland fauna, elements of which can be quite mobile, to track habitat conditions over time and persist over the long-term within the same local area. Manipulation of wetland hydrology also has been used to manipulate salinity in coastal areas by blocking natural drainages, thereby permitting the fresh water that accumulates to leach out salt. The resultant shift in plant communities to more salt-intolerant species also changes wildlife communities.

In addition to water-level manipulation, a number of artificial procedures can be used to modify wetlands to enhance wildlife habitats. These include creation of openings in dense emergent vegetation through cutting, application of herbicides or, more permanently, by blasting. Planting of select forage species is sometimes attempted but is usually expensive and rarely successful. Provision of artificial nest sites for select species, especially ducks, has been one of the most common and visible forms of wetland management to benefit wildlife. Artificial nesting and loafing sites can be constructed for birds. Large, whole tree boles, including partially hollowed-out trees, can be placed within or adjacent to the restoration site. While perhaps aesthetically pleasing, the overall contribution of such efforts to boost local populations is at best modest given the small fraction of regional populations that can be supported by such structures. These artificial procedures, in general, are expensive and time-consuming and

should be considered a minor complement to a larger strategy of natural management that uses hydrological manipulation to produce habitat changes over large areas in a cost-effective manner.

The tradeoffs between community types must be articulated and considered in management and planning. For example, flooding bogs and meadows to produce marshes, a not uncommon occurrence in North America, entails losses of certain species, many rare or unusual, and gains of others, many common and sought after by recreational users. In general, maintaining wetlands in a productive and natural state that meets the needs of the entire wetland fauna is more likely to meet diverse public needs than is species-specific management (e.g., for waterfowl only).

Conclusions

Despite lack of systematic comparisons, the existing scientific literature on wetland ecosystems is unambiguous in conveying the high level of diversity supported by wetlands. The source of this high diversity lies in the exceptionally large number of different types of wetlands that occur worldwide. Because wetlands occur on every continent except Antarctica, in every climatic region, in most biogeographic regions of the globe, and in a wide array of geological and topographic settings, the number of different types of wetlands created by the myriad combinations of these factors is very large and has yet to be catalogued. The extraordinary richness of plant and animal species that depend on wetlands arises from this diversity of types. Relative to the area they occupy, wetlands support a disproportionately large fraction of the world's rare, endangered, and threatened plant and animal species. Maintaining the high diversity of wetland species means maintaining a high diversity of wetland types.

Biodiversity and Human Health

Richard S Ostfeld, Cary Institute of Ecosystem Studies, Millbrook, NY, USA

Felicia Keesing, Bard College, Annandale-on-Hudson, NY, USA

Published by Elsevier Inc.

Glossary

Dilution effect The phenomenon whereby increases in biodiversity are associated with decreases in the transmission, risk, or incidence of infectious disease.

Disease incidence The number of new cases of a disease per population per unit time, often expressed as a rate.

Disease prevalence The number of disease cases per population.

Horizontal transmission The transmission of pathogens within single generations of hosts.

Infection prevalence The number of infections (or infected individuals) per population.

Infectious disease State of compromised health in a host caused by a pathogen infection.

Reservoir competence The degree to which a host is capable of supporting pathogen proliferation and transmission to other hosts or to vectors.

Vector (of pathogen) An animal, typically an arthropod, which transmits pathogens from one host to another.

Vertical transmission The transmission of pathogens across generations of hosts.

Zoonosis Disease of humans caused by pathogens that proliferate within and are transmitted from nonhuman vertebrate animals.

Introduction

Biodiversity – the variety of biological entities, from genes to species to ecosystems – is a very broad concept. With such a broad definition, it seems obvious that human health depends on biodiversity. From the plant and animal fibers we wear, to the plants, animals, and fungi we eat, to the natural compounds we use to treat infections, there is no aspect of human health and well-being that does not rely directly or indirectly on the variety of life. Even many synthetic materials are modeled after natural products. But we also sense – indeed, we have direct evidence that not every change in the earth's biodiversity results in a detectable change in human health. The loss of particular genes or species from natural ecosystems might be irrelevant to human health, whereas the loss of others could be cataclysmic. The loss of harmful organisms, such as smallpox virus, certainly is an example of biodiversity loss, yet it would be likely to increase human health. To analyze the effects of biodiversity loss or biodiversity change on human health, it is necessary to subdivide the breadth of biodiversity into component parts. It is also useful to subdivide human health into components in order to understand how specific aspects of biodiversity affect specific aspects of human health.

Subdividing Biodiversity

Scientific study of the linkages between biodiversity and human health has focused predominantly on species diversity, with some research pursuing the role of genetic diversity, and very little focusing on diversity among ecological communities or within entire ecosystems. This review will focus on how changes in species diversity affect human health. Species diversity is typically defined in one of two different ways. Species richness is the number of different species that occurs in a defined area. In practice, estimates of species richness (or any other metric of species diversity) are typically restricted to a particular

taxonomic group (e.g., trees and mammals), or a particular trophic level (e.g., primary producers and herbivores). Species evenness is a measure of the relative abundances of species within a community. Quantitative metrics of species diversity, such as the Shannon Index or Simpson Index, combine both species richness and species evenness to derive a value that characterizes a community. So for instance, a three-species community in which each species has 33% of the individuals would be considered more diverse (higher evenness) than another community with the same three species but in which one species constitutes 95% of the community. In addition to the number of species and their relative abundances, the identity of species can be critical in understanding the importance of biodiversity. As natural communities change in biodiversity (species richness or evenness), it matters which species are added or lost. This is because species tend to vary strongly in their functional roles. Moreover, species tend to have vastly different probabilities of disappearing from communities as biodiversity is lost or of invading communities as biodiversity increases. Therefore, a critical aspect of biodiversity is the species composition of communities.

When asking how species diversity affects human health, then, it is necessary to be clear about which measure of biodiversity we are considering. An additional complexity is that the three aspects mentioned above – richness, evenness, and composition – are often interrelated in natural systems. For example, we can return to our three-species hypothetical community, with each species comprising 33% of the individuals. If one species is lost and the remaining two do not change in relative abundance, then richness will decline without a concomitant decline in evenness. However, because species in communities typically interact, the loss of one species is likely to affect the remaining species differently, such that one increases in abundance at the expense of the other. In this example, species richness and evenness would be interdependent. This effect is magnified by the fact that species within ecological communities have vastly different

probabilities of declining or disappearing as biodiversity is lost. For example, large-bodied animals, dietary specialists, predators, and rare species are much more likely to disappear from communities than are smaller animals, generalists, herbivores or omnivores, and abundant or widespread species. This example illustrates that species richness, species evenness, and species composition are interdependent.

Until recently, the predominant focus in the literature about diversity and human health has been on the effects of the disappearance of individual species rather than on biodiversity, which is an aggregate measure of multiple biological entities. Below the literature has been included on how individual species, or groups of species, affect human health only when those species are relevant to biodiversity by virtue of being under threat of serious decline or extinction.

Subdividing Human Health

Different components of biodiversity can affect different components of human health. The impact of changes in biodiversity on human health can be organized into four categories. First, changes in biodiversity can affect scientists' abilities to conduct basic research in the biomedical sciences. This occurs when species that are or might be useful as animal models of human health are affected by drivers of biodiversity loss. Second, the development of future treatments for human disease can be strongly affected by biodiversity loss. A large percentage of current treatments (e.g., pharmaceutical drugs) was derived from biological species, some of which are threatened with decline or extinction. Much effort is also spent to discover biological species or compounds that can serve as sources of preventative or curative therapies, and biodiversity loss threatens such discovery. Third, humans rely on many different plant, animal, and microbial species for food, and the loss of biodiversity can affect health through the direct and indirect impacts of nutrition. The diversity of current and potential food species takes on additional importance as climate change alters the conditions under which many of our currently used crops and livestock were selected. Degrading environmental conditions will increase the necessity for incorporating diverse species and genotypes into human nutrition. Fourth, changes in biodiversity can affect the abundance, distribution, and transmission dynamics of infectious agents that attack humans, livestock, or crop plants, with strong consequences for human health.

To reflect the major research foci developing in the past 10–15 years, the authors will describe how changes in biodiversity affect: (1) basic biomedical research; (2) identification and development of preventative and therapeutic agents; (3) nutrition; and (4) risk and incidence of infectious diseases.

Biodiversity and Basic Biomedical Research

Nonhuman animals have served as models of human biomedical research for centuries. In some respects, each such use of a nonhuman model could be considered relevant to a discussion of biodiversity and human health because all these

model organisms contribute to the earth's biodiversity. In other respects, however, most of the traditional model organisms are not highly relevant to discussions of the interactions between biodiversity and human health because they are not imperiled and because they are constructs of human genetic modification and do not represent natural biodiversity. Examples of the latter include the many laboratory genotypes of the laboratory mouse *Mus musculus*, the lab rat *Rattus norvegicus*, the fruit fly *Drosophila melanogaster*, and the roundworm *Caenorhabditis elegans*. But in the case of non-traditional models of human biology and medicine, some species are themselves imperiled or belong to taxonomic groups of which some members are of conservation concern. Below the authors will discuss two examples of how these species have contributed or might contribute to a basic understanding of human disease. The underlying theme is that some wildlife species are able to perform functions that solve physiological challenges similar to those humans also face. Further study of these adaptations is likely to lead to a better understanding of, and solutions to, human diseases of various kinds. Continued declines in biodiversity could foreclose these opportunities to improve public health.

Bears and Human Physiology

Most species of bear (Family Ursidae) undergo long periods of seasonal quiescence called "denning" or hibernation. Hibernation by bears differs from that of "true hibernators" (e.g., some bats, ground squirrels, and dormice) in that bear body temperatures decline by only a few degrees but not to ambient and bears are easily awakened. Bear hibernation can continue for many months, during which the bears do not eat, drink, urinate, or defecate, and they do not even move at all. To contend with the accumulation of urine, which continues during hibernation, bears transport urine through the lining of the bladder into the bloodstream, where the urea is degraded into amino acids that can be used to synthesize proteins (Chivian and Bernstein, 2008). Buildups of urea characterize human patients with end-stage renal disease, which is currently treatable only with dialysis or kidney transplantation. Considerable interest exists, therefore, in understanding the physiological mechanisms by which bears recycle urea into proteins so that treatments for human renal disease can be developed.

Nutritional deficiencies and immobility by humans can cause dramatic loss of bone mass leading to osteoporosis, which is a major public health problem worldwide. In bears, however, the months of fasting and immobility during hibernation do not cause a loss of bone mass, because bears recycle the calcium lost from bone back into forming new bone (Chivian and Bernstein, 2008). Apparently, hibernating bears are able to down-regulate the activity of osteoclasts, cells that help regulate bone resorption, and up-regulate osteoblasts and fibroblasts, cells that form new bone and cartilage, respectively (Chivian and Bernstein, 2008). The biochemical extract responsible for these regulatory activities in bears has reversed bone loss in ovariectomized rats, which simulates treatment for osteoporosis in postmenopausal women (Chivian and Bernstein, 2008).

As large-bodied predators, bears are more vulnerable to extinction than are smaller-bodied animals and those at lower trophic levels. Consequently, the ability of scientists to make use of the unique adaptations of bears for the betterment of human health is vulnerable.

Cone Snails and Human Physiology

The genus *Conus* is a speciose group of mostly tropical marine snails with many members that are probably rare and perhaps in danger of extinction (Chivian and Bernstein, 2008). Too little is known about their abundance and population trends to accurately characterize their conservation status, but many occupy sites (coral reefs and mangrove habitats) that are being destroyed and degraded at a rapid pace, and many are subject to unregulated collecting by amateur malacologists. Cone snails are predators that capture mobile prey (e.g., fishes) by harpooning them with a specialized “tooth” that contains a cocktail of toxic peptides. Each species of *Conus* apparently has a unique mixture of > 100 such peptides and the entire genus might produce as many as 100,000 different toxic peptides (Chivian and Bernstein, 2008). Although these peptides, called conopeptides, have a common impact on their victims – paralysis – each appears to have a different mechanism of action by virtue of an affinity for different cell surface receptors. Many act by blocking ion channels that control concentrations of ions such as sodium, potassium, calcium, and chloride on each side of the cell membrane. Because controlling the flux of ions to and from cells is critical for many physiological functions, the nature and mechanism of action of conopeptides is a fertile ground for basic biomedical researchers. For example, recently a conopeptide was discovered that has a highly specific, strong affinity for a particular type of acetylcholine receptor in vertebrate nervous systems and muscle cells. Acetylcholine receptors control ion channels responsible for regulating nerve cell impulses, but many such receptors exist, each with a different regulatory function. The newly discovered conopeptide’s extreme specificity for a particular acetylcholine receptor suggests that other conopeptides will be similarly highly specific. Having a diverse group of highly specific peptides should pave the way for basic research into the proximate causes of diseases in which abnormal acetylcholine regulation plays a key role, including Parkinson disease, Alzheimer disease, epilepsy, and alcoholism (Chivian and Bernstein, 2008).

Biodiversity and Preventative/Therapeutic Agents

Humans have used natural compounds as medicines since antiquity. In modern times, active compounds from plants, animals, and microbes are important worldwide in both scientifically evaluated and “traditional” medicines. At least half of the most prescribed medicines in the USA contain active compounds directly or indirectly derived from natural sources (Newman *et al.*, 2008). The enormous diversity of chemical compounds produced by the earth’s biota constitutes a rich source of molecules of potential use in protecting or improving human health. Discovery of natural compounds that could be used as medicines proceeds either by targeted

screening or by untargeted screening, the latter of which requires enormous numbers of species to be tested because the odds of each individual species containing useful compounds are so low, (Newman *et al.*, 2008). Screening can be targeted by using prior information about traditional human use of particular organisms to solve specific health problems (e.g., Rosenthal and Preszler, 2002). Screening can also be targeted by focusing on species whose natural histories suggest that they share pathogens or other health challenges with humans. For example, saprophytic bacteria and fungi often compete for resources, and both types of microbes might be expected to produce chemical compounds that inhibit their competitors. Consequently, antibacterial agents are often sought in certain fungi, and antifungal and antibacterial agents are often sought in certain types of bacteria.

Newman *et al.* (2008) provide many examples of plants, animals, and microbes that produce compounds that scientists have developed into medicines. Examples of plants include the analgesic morphine from opium poppies (*Papaver somniferum*); vincristine and vinblastine as highly potent anticancer compounds from rosy periwinkle (*Catharanthus roseus*); the precursor of aspirin in willows (*Salix* spp.); and the anti-HIV drugs called calanolides from tropical trees of the genus *Calophyllum*. Examples of animals include potent anticoagulants from medicinal leeches (*Hirudo medicinalis*) and canine hookworms (*Ancylostoma caninum*), and angiotensin-converting-enzyme (ACE)-inhibiting compounds instrumental in controlling hypertension that were initially discovered in the venom of a pit viper *Bothrops jararaca*. Examples from microbes include penicillin and its many derivatives, initially found in *Penicillium notatum* molds; the aminoglycoside antibiotics (including streptomycin) from an actinomycete bacterium *Streptomyces griseus*; and the cholesterol-controlling statins, initially isolated from several *Penicillium* species.

Although the organisms mentioned above have provided compounds of enormous benefit to human health and well-being, none are imperiled or of conservation concern, a fact that complicates the argument that these are examples of strong connections between biodiversity and human health. However, the sheer number of medically useful natural compounds already discovered (Newman *et al.*, 2008; Rosenthal and Preszler, 2002) combined with the tiny fraction of species that have been thoroughly screened for such compounds, and the precipitous loss of biodiversity worldwide, together suggest that we are rapidly losing potential sources of medicines as biodiversity declines.

Biodiversity and Nutrition

Biodiversity is essential for the production of both plant-based and animal-based foods. Throughout history, wild plants and animals have been chosen for domestication and selectively bred to improve desirable traits. Biodiversity in agroecosystems can affect human health through several mechanisms, including increased resistance to pests and pathogens, insurance against current and future environmental changes, improved nutrition through dietary diversity, and better immune defenses against infectious diseases.

Monocultures of genetically similar or identical crops are notoriously vulnerable to massive disease-caused failures, because pathogens can encounter huge numbers of susceptible hosts leading to rapid spread (Elton, 1958; Keesing *et al.*, 2006). Examples of monoculture crop disasters that have been caused by pathogens include wheat failures during ancient Roman times caused by stem rust (*Puccinia graminis*), destruction of rye crops due to ergot poisoning during Europe's Middle Ages, the decimation of French grape vineyards caused by downy mildew disease, and the Irish potato famine of the mid-nineteenth century, caused by *Phytophthora infestans* (Hillel and Rosenzweig, 2008). Experimental plantings of diverse polycultures of different strains of rice have vastly reduced the burden of rice blast disease in China, avoiding the need for massive fungicide application and improving productivity and profits (Zhu *et al.*, 2000). Although in recent years genetic engineering has emerged as a means of adding genetic variants to produce desirable traits such as pest resistance, drought resistance, or nutritional value, the creation of genetic variants through cross-breeding with wild relatives remains an essential means of improving crops.

Current agricultural productivity and resistance to pests and pathogens can be increased by both genetic diversity within populations of plants and animals already used for agriculture and by species diversity of related wild plants and animals. This diversity is also likely to be critical in confronting future environmental challenges arising from climate change, introduced pests, emerging pathogens, and nutrient-depleted soils. Traits that support high productivity under current environmental conditions are not likely to support equally high productivity as those conditions change, because of trade-offs among specific adaptations. These observations should serve as a caution to agronomists. Because strong selection reduces genetic diversity by promoting some alleles at the expense of others, and because only relatively few plant and animal species are currently profitable, modern agricultural practices tend to erode crop biodiversity (Hillel and Rosenzweig, 2008).

A recent study in western Kenya showed that farms with higher diversity of edible plant species provided a greater diversity of essential nutrients, including protein, carbohydrates, vitamins A and C, iron, zinc, and folate (DeClerck *et al.*, 2011). Low nutritional diversity of crop plants within these agricultural fields was associated with high rates of anemia among associated community members, whereas high nutritional diversity of crop plants within these agricultural fields was strongly correlated with the absence of anemia (DeClerck *et al.*, 2011).

Crops that require animal pollination comprise about one third of agricultural food production globally (Klein *et al.*, 2007). Biodiversity loss in guilds of both avian and mammalian pollinators can compromise crop production, especially from tropical fruit trees (Kunz *et al.*, 2011; Whelan *et al.*, 2008). But more importantly, the loss of insect pollinators, especially native bees, from many ecosystems is causing extensive declines in pollination success and hence yields of vegetable and fruit crops globally (Kremen and Ostfeld, 2005; Potts *et al.*, 2010; Winfree, 2010). Insufficient levels of pollination caused by the loss of insect pollinators have caused declines of up to 70% in crop productivity (Hillel and Rosenzweig, 2008).

Biodiversity and Infectious Disease

Four recent reviews of the scientific literature have revealed many cases in which high biodiversity is associated with low risk or incidence of infectious disease, and conversely, many cases in which biodiversity loss is associated with increased disease risk or incidence (Johnson and Thielges, 2010; Keesing *et al.*, 2006, 2010; Pongsiri *et al.*, 2009). Basic epidemiological models of a simplified system consisting of a single host species and a single pathogen specialized on that host show at least five mechanisms by which adding one or more species to the system (increasing diversity) can reduce the spread of infection (Keesing *et al.*, 2006). Increased diversity can reduce transmission by: (1) reducing the rate of encounter between susceptible and infectious individuals, a mechanism termed encounter reduction; (2) reducing the probability of pathogen transmission when encounters do take place (transmission reduction); (3) decreasing the abundance of susceptible individuals (susceptible host regulation); (4) increasing the recovery rate of infected individuals (recovery augmentation); and (5) increasing the death rate of infected individuals (infected host mortality) (Figure 1). In disease systems in which a vector (usually an arthropod such as a mosquito or tick) is important in transmitting pathogens, an additional mechanism can occur. In these systems increased diversity can: (6) decrease the abundance of vectors (vector regulation). In addition, in these vector-borne disease systems, increased diversity can reduce encounter rates between vectors and either infected or susceptible hosts, leading to a second form of encounter reduction (*see* Conceptual Antecedents). Wide-spread support exists for three of these mechanisms: encounter reduction; susceptible host regulation, and vector regulation; whereas studies of the other mechanisms are largely lacking. Although in theory increased diversity could increase risk or incidence of infectious diseases, empirical studies demonstrating such an effect are rare (Keesing *et al.*, 2010).

The phenomenon whereby increased diversity decreases disease transmission has been termed the "dilution effect" (Norman *et al.*, 1999; Ostfeld and Keesing, 2000a, b; Vanbuskirk and Ostfeld, 1995), and the reverse phenomenon has been termed the "amplification effect" (Keesing *et al.*, 2006). In the following sections the author will describe some historical antecedents to the notion that high biodiversity reduces disease transmission, followed by discussions of specific diseases in which biodiversity has been shown to reduce pathogen transmission, in each case referring to the underlying mechanisms whenever these are known.

Conceptual Antecedents

An important precursor to the modern study of the relationship between biodiversity and infectious disease transmission is the notion of zooprophylaxis, which the World Health Organization (Organization, 1982) defined as "the use of wild or domestic animals, which are not the reservoir hosts of a given disease, to divert the blood-seeking mosquito vectors from the human hosts of that disease." This definition, which follows an earlier treatment by (Brumpt, 1944–1945),

Figure 1 Conceptual model of the mechanisms by which diversity could reduce disease risk in a specialist host-pathogen system for a non-vector-borne disease. The original community consists of a single species with some individuals infected (filled circles) and some individuals uninfected and therefore susceptible (open circles). Each individual uses a particular home range (dashed lines). The addition of a second species (black squares) could (a) result in a reduction in space use by the host species, thus reducing encounters between susceptible and infected individuals (encounter reduction); (b) reduce the probability of transmission given encounters, as indicated here by no increase in the number of infected individuals despite contacts that could lead to transmission (transmission reduction); (c) reduce the number of susceptible hosts (susceptible host regulation); (d) increase the rate of recovery of infected individuals, as indicated by some infected individuals becoming uninfected (recovery augmentation); or (e) increase the mortality rate of infected individuals (infected host mortality). Redrawn from Keesing F, Holt RD, and Ostfeld RS (2006) Effects of species diversity on disease risk. *Ecology Letters* 9: 485–498. doi: DOI 10.1111/j.1461-0248.2006.00885.x, with permission from Nature.

implies that diversity has increased via the addition of non-human animals and that the mechanism of reduced disease transmission is the diversion of vector blood meals away from humans. Note that according to this definition, zoonophylaxis is a manifestation of encounter reduction pertaining specifically to mosquitoes, although the concept has sometimes been extended to other arthropod vectors of human pathogens (Service, 1991). Therefore, zoonophylaxis is not equivalent to the dilution effect, but rather describes one manifestation of one of the five specific mechanisms by which the dilution effect can operate. Another precursor to modern study of the dilution effect is Elton's (Elton, 1958) recognition that plant diseases are reduced in intensity or distribution in more diverse plant communities, especially when that higher diversity reduces the population density of the host plant. Note that this concept of a protective effect of diversity on disease transmission is a manifestation of susceptible host regulation (Keesing et al., 2006). For decades or centuries before Elton, agronomists have used various forms of intercropping (the practice of growing mixtures of crop plants, either simultaneously or sequentially) to increase yields. One of the main mechanisms by which crop diversity can increase yields is by

reducing abundance of or attack rates by plant pathogens (Altieri, 1999).

Lyme Disease

Lyme disease is caused by the spirochete bacterium *Borrelia burgdorferi*, which is transmitted among wildlife hosts and from wildlife to humans via the bite of an ixodid tick. In Europe and Asia the main vectors are *Ixodes ricinus* and *Ixodes persulcatus*, respectively, and in North America, the main vector is the blacklegged tick *Ixodes scapularis*. Because *Ixodes* ticks do not transfer the bacterium from mother to offspring, each new generation of larval ticks hatches free of infection. After hatching from eggs, larval ticks take a single 3–4-day-long blood meal from a vertebrate host, during which they can acquire infection with *Bo. burgdorferi* if the host itself is infected. This larval blood meal is also critical in determining whether the tick survives to the next stage – the nymph – because larvae attempting a blood meal are susceptible to host grooming, which is an important cause of mortality (Keesing et al., 2009). Nymphal ticks are responsible for transmitting infection to both reservoir hosts and human victims (Ostfeld,

2011). The risk to people of contracting Lyme disease is strongly correlated with the abundance of infected nymphal ticks in the environment (Ostfeld, 2011).

Vertebrate biodiversity is important in determining both the abundance of nymphal ticks and the proportion of nymphs that are infected with *Bo. burgdorferi*. Blacklegged ticks will readily attempt to feed on dozens of different species of mammals, birds, and lizards. Indeed, they have been reported infesting > 112 different host species (Keirans *et al.*, 1996). Larval ticks appear to “prefer” some hosts more than others when offered a choice in a laboratory setting (Shaw *et al.*, 2003; Slowik and Lane, 2009), but these preferences tend to be weak, and the ticks’ extraordinarily wide distribution among hosts underscores their lack of specificity in host associations. The abundance (intensity) of larval ticks on any particular host appears to be quite sensitive to the availability of alternative hosts in the community. For example, Brunner and Ostfeld (2008) showed that, as the population density of one important host, the eastern chipmunk (*Tamias striatus*), decreased, the abundance of larval ticks on another key host, the white-footed mouse (*Peromyscus leucopus*), increased up to 20-fold. Apparently, because these ticks are only weakly motile and require a host to draw near in order for them to attach, the relative abundances of different hosts strongly affect encounter rates between ticks and those hosts and thus the distribution of larvae across the host community.

Different species of hosts have vastly different probabilities of supporting blood feeding by ticks and tick survival, and ticks feeding on different hosts have different probabilities of acquiring infection with the Lyme disease agent. Among mammal and bird hosts that are commonly parasitized by blacklegged ticks in the eastern USA, the white-footed mouse is the host most likely to support tick survival during blood feeding (Keesing *et al.*, 2009), overwinter survival after the blood meal (Brunner *et al.*, 2011), and acquisition of *Bo. burgdorferi* spirochetes (LoGiudice *et al.*, 2003, 2008). Chipmunks and shrews are intermediate in most respects, and most other members of the host community tend to be poor hosts and poor reservoirs for the Lyme disease bacterium. Therefore, white-footed mice play a critical role in the risk of human exposure to Lyme disease. The abundance of infected nymphal ticks is strongly correlated with the population density of mice in space and time (Ostfeld *et al.*, 2006). As nonmouse hosts are added to, or increase in abundance in, host communities, the risk of human exposure to Lyme disease declines (Ostfeld and Keesing, 2000a; Schmidt and Ostfeld, 2001).

White-footed mice are highly resilient to anthropogenic and natural disturbance and are often most abundant in disturbed, degraded, or fragmented habitats, including suburban and exurban homes (Ostfeld, 2011). This high ecological resilience seems to be facilitated by extreme habitat and dietary generalization, small body size, strong dispersal ability, and high reproductive potential. Other vertebrates that are more specialized, larger bodied, weaker dispersers, and slower in reproductive rates tend to decline or disappear in highly disturbed, degraded, or fragmented habitats. A critical consequence of these differences in ecological resilience is a tendency for mice to persist, and even thrive, when vertebrate biodiversity is lost (LoGiudice *et al.*, 2008; Ostfeld, 2011).

Thus, low-diversity vertebrate communities typically contain abundant mice but few other species, whereas high-diversity communities contain mice and many other species in high relative abundances. These selective declines or local extinctions of host species that tend to buffer Lyme disease transmission appear to underlie the observation that highly fragmented landscapes and small forest fragments maintain the highest abundances of infected blacklegged ticks (Allan *et al.*, 2003; Brownstein *et al.*, 2005; Jackson *et al.*, 2006) (Figure 2).

Observations from the Lyme disease system allowed Ostfeld and Keesing (Ostfeld and Keesing, 2000a) to characterize the general features that are necessary and sufficient to produce a dilution effect (i.e., a negative correlation between biodiversity and disease risk) in any vector-borne disease system. The conditions are: (1) a vector must be at least somewhat generalized in its choice of hosts (i.e., a nonspecialist). The more specialized the vector is on one or a few hosts, the less important overall diversity of the host community will be. (2) The pathogen must rely largely on host-to-vector transmission rather than on vertical transmission across generations of vectors. For pathogens that are efficiently transmitted transovarially (from mother vector to offspring), host-to-vector transmission is relatively less important in determining infection prevalence and therefore transmission risk. (3) The various host species from which the vector feeds must differ in their “reservoir competence,” or their probability of infecting a feeding vector in nature. If host species were interchangeable in their reservoir competence, then the identity of the blood meal host, and hence host diversity, would not matter to transmission dynamics. More recently, Keesing *et al.* (2009) added a correlate of condition (3), namely that the various host species differ in their “permissiveness” to vector feeding, or their probability of allowing the vector to feed successfully versus killing it during grooming. (4) The host species most likely to successfully provide the vector with a blood meal and to infect it must be those that persist in species-poor communities. If the most competent reservoir hosts tended to occur only in the most diverse communities, then high-diversity ecosystems would produce the highest risk – the opposite of the dilution effect. When these four conditions are met, vectors co-occurring with low diversity host communities will tend to bite the most competent reservoirs and the most permissive hosts, leading to higher abundance and/or infection prevalence in the vector population. The consequence will be heightened risk of transmission to people. Ample evidence now exists to support the widespread occurrence of these four conditions, which indicates that the dilution effect is a general phenomenon (Keesing *et al.*, 2010).

West Nile Virus (WNV)

WNV is a flavivirus (relative of the yellow fever virus) that is amplified in certain species of birds and transmitted among wildlife hosts by mosquitoes, predominantly members of the genera *Culex* and *Aedes*. When mosquitoes infected with WNV bite humans, serious illness or death can result. The virus was restricted to parts of Africa, Asia, and Europe until 1999 when it was inadvertently introduced into the New York City area.

Figure 2 The total density of nymphal blacklegged ticks *Ixodes scapularis* (a) percentage of nymphs infected with *B. burgdorferi* (b) and density of infected nymphs (c) in 14 forest fragments of Dutchess County, New York. Reprinted from Allan BF, Keesing F, and Ostfeld RS (2003) Effect of forest fragmentation on Lyme disease risk. *Conservation Biology* 17: 267–272, with permission from Wiley.

A mere 3–4 years after its appearance in New York the virus had dispersed all the way across North America to the west coast, causing illness or death in tens of thousands of people and countless wild birds as it spread. Throughout much of North America, it remains a serious health threat to both people and native avifauna (Allan *et al.*, 2009; Kilpatrick *et al.*, 2006a; LaDeau *et al.*, 2007, 2008).

The WNV system shares some important features with the Lyme disease system. The virus relies predominantly on

horizontal (host to vector to host) transmission rather than on vertical (transovarial) transmission across generations of mosquitoes. Therefore, similar to Lyme disease, the prevalence of infection in the vector depends on which hosts are bitten and how likely those hosts are to transmit the pathogen to the feeding mosquito. Unlike the Lyme disease system, in which tick abundance is determined at least partly by the abundance of some hosts, mosquito abundance appears to be less dependent on host abundance and more dependent on the availability of aquatic breeding sites (Dobson, 2004). This independence of vector abundance from host abundance simplifies the system in that the major impact of hosts is on vector infection prevalence rather than on vector abundance. Similar to the tick vectors of Lyme disease, the mosquitoes that transmit WNV are host generalists – they readily take blood meals from many different species of birds, mammals, and reptiles within ecological communities (Kilpatrick *et al.*, 2007; Komar *et al.*, 2003; LaDeau *et al.*, 2008; Marra *et al.*, 2004). *Culex* and *Aedes* mosquitoes do show preferences for some hosts more than others (Kilpatrick *et al.*, 2006b), and their high mobility relative to ticks means that they can more readily reject potential hosts that are less preferred. Nevertheless, at the population level, it is clear that vector mosquitoes bite most or all available members of the vertebrate community. Within West Nile-endemic zones, ample evidence indicates that infection is widespread among birds, mammals, and some reptiles (LaDeau *et al.*, 2007, 2008; Marra *et al.*, 2004), confirming that the vectors are generalists despite having host preferences.

Similar to the Lyme disease system, the various hosts for mosquitoes differ dramatically in their ability to support replication by the pathogen, the length of time they remain infected, and their probability of transmitting virus to feeding mosquitoes (Komar *et al.*, 2003). Although studies at different localities sometimes implicate different bird species as reservoirs, the general pattern is that American robins, house sparrows, common grackles, American crows, blue jays, and house finches are the most competent reservoirs for WNV within bird communities. Many other passerines (songbirds), nonpasserines, mammals, and reptiles, either fail to permit the virus to amplify sufficiently, producing very low concentrations of virus in their blood (low viremia) or they permit a high viremia but for only a very brief period. Either of these two processes will make these bird species inefficient at transmitting the virus to mosquitoes and therefore cause them to be incompetent reservoirs.

Ezenwa *et al.* (2006) were the first to test for an association between avian diversity and the prevalence of WNV in mosquitoes and humans. They reasoned that, because nonpasserine birds were generally incapable of producing high viremias, the presence of a high diversity of these bird species should cause mosquitoes to feed predominantly on poor reservoir hosts, reducing transmission rates of WNV from host to vector. To test this hypothesis, they captured hundreds of batches of *Culex* mosquitoes from West Nile-endemic sites in eastern Louisiana where they also estimated species richness in the local bird communities. They found that the proportion of mosquitoes infected with WNV was strongly negatively correlated with species richness of nonpasserines and uncorrelated with species richness of passerines. An interesting

additional result was that the population density of infected *Culex* mosquitoes was also negatively correlated with nonpasserine diversity, suggesting that nonpasserines might be killing mosquitoes that attempt to feed (similar to what Keesing *et al.* (2009) observed for ticks and Lyme disease). In addition, examining county-specific data throughout Louisiana, Ezenwa and colleagues found that the incidence of West Nile disease in humans was negatively correlated with species richness of nonpasserines in that county (Figure 3).

Three subsequent studies also found strong support for a dilution effect in WNV, although in all these cases it was species diversity of passerines that reduced virus prevalence. Swaddle and Calos (2008) selected 65 adjacent pairs of counties in the eastern USA such that each pair consisted of one county with human cases of West Nile encephalitis and an adjacent county without. They tested the hypothesis that the West Nile-negative county in each pair would contain higher bird species diversity, as measured by the Breeding Bird Survey data from the United States Geological Survey. Indeed, Swaddle and Calos found that the pairs of counties with the largest difference in bird diversity also had the largest difference in prevalence of West Nile encephalitis, with higher bird diversity being correlated with lower disease in humans.

Allan *et al.* (2009) examined human incidence of West Nile disease and bird diversity from 742 US counties within 38 states during years 2002–2004 of rapid, cross-country spread. They calculated bird diversity from the Breeding Bird Survey data using the Shannon Diversity metric, which emphasizes both species evenness and richness. First, they calculated the total “community competence” of birds by multiplying the abundance of each species by its reservoir competence and summing the species-specific totals. Community competence provides an estimate of the likelihood that a particular bird community will produce infected mosquitoes. They found that species diversity of bird communities was strongly negatively correlated with community competence, a result that parallels that in the Lyme disease system. In other words, host communities with low diversity tend to be biased toward highly competent reservoirs, whereas high diversity communities contain poorer reservoirs. By comparing different models for explaining the variation among counties in West Nile disease, Allan and colleagues found that bird diversity was the strongest and most consistent factor – counties with low avian diversity had, on average, much higher rates of West Nile disease than did those with high diversity (Figure 4).

Koenig *et al.* (2010) examined the role of bird diversity in population declines of American crows during the initial

Figure 3 Various measures of risk of human exposure to mosquitoes infected with West Nile virus as a function of the species richness of songbirds (passerines) and nonpasserine birds. Both the infection prevalence of mosquitoes (maximum likelihood estimate (MLE)) and the density of infected mosquitoes (DIM) strongly, negatively correlated with species diversity of nonpasserines, but were unrelated to species diversity of passerines. Reprinted from Ezenwa VO, Godsey MS, King RJ, and Guptill SC (2006) Avian diversity and West Nile virus: Testing associations between biodiversity and infectious disease risk. *Proceedings of the Royal Society B-Biological Sciences* 273: 109–117. doi: DOI 10.1098/rspb.2005.3284, with permission from Royal Society of Publishing.

Figure 4 Negative correlations between the number of human cases of disease caused by West Nile virus in an American county and the average species diversity of birds in that county as determined by the breeding bird survey. See [Allan et al. \(2009\)](#) for details. 5-year sweep of WNV across USA. Crows can experience rapid mortality after infection resulting in severe population declines as WNV invades new areas ([LaDeau et al., 2007](#)); therefore crow population declines are a good proxy for transmission rates within wildlife communities. Koenig and colleagues quantified the severity of crow declines using the Breeding Bird Survey data for individual survey routes conducted before and after invasion by the virus. They then tested the ability of several factors to explain the severity of crow declines, including: the year WNV was first detected in the state; population density of crows; bird diversity (Shannon index); urbanization (estimated by human population density); total number of individual birds; mean rainfall; mean maximum temperature; and a measure of spatial self-correlation in the data (to represent the likelihood that closer sites are more similar). The causal variables best supported by the data were bird diversity (crows were more likely to decline where bird diversity was low), urbanization (crow declines were more likely in more urbanized areas), and crow density (declines were more likely where initial crow density was high). They found some evidence that areas hit earlier by WNV tended to show more pronounced crow declines, but there was little support for effects of total bird abundance, rainfall, or temperature. The patterns were spatially self-correlated.

[Hamer et al. \(2011\)](#) examined the relationship between bird diversity and WNV infection in *Culex pipiens* mosquitoes in Chicago, IL. They assessed mosquito abundance and infection prevalence, total bird diversity (richness and Shannon index), and the diversity of the birds from which the mosquitoes fed based on molecular diagnostic tests of blood in captured mosquitoes. These data allowed them to test the hypothesis

that selective feeding by the mosquitoes was strong enough to weaken the effect of the diversity of available bird hosts. If feeding preferences are sufficiently strong, host availability will be less important. Hamer and colleagues estimated each bird species' contribution to the pool of infected mosquitoes by calculating host-specific "force of infection" (the squared fraction of total blood meals taken from a host species times that species' reservoir competence), which also allowed them to calculate "community force of infection" by summing across all host species present at a site. Of the 23 sites in which all data were collected, 11 had sufficient samples of bird-fed mosquitoes for statistical analysis of all factors. Although they found strong apparent host preferences overall, these preferences differed among sites, suggesting that preferences are not fixed but might vary with local host availability. In addition, it is important to note that true feeding preferences (i.e., the degree of bias in the distribution of attempted feedings compared to the availability of hosts) might not be revealed by analyzing only those mosquitoes that successfully fed. Successful feedings undoubtedly represent a subset of feeding attempts. If some hosts for mosquitoes are better able to defend themselves against mosquitoes, potentially causing mosquito mortality (as has been shown for ticks and their hosts: ([Keesing et al., 2009](#))), then the distribution of successful feedings across host availability could distort true preferences considerably.

In Hamer and colleagues' study, diversity of birds available and diversity of birds represented in the blood-fed mosquitoes were not correlated. Hamer and colleagues used a maximum likelihood statistical approach to compare explanatory models of mosquito infection prevalence with WNV. Interestingly, despite apparently strong host preferences by mosquitoes, the best supported model invoked an interaction between bird diversity and the community force of infection. The majority of infected mosquitoes had fed on American robins, house sparrows, and house finches, species that tend to reach high abundance in low-diversity communities ([Allan et al., 2009](#)). A plausible interpretation of these results is that selective feeding by mosquito vectors causes a multiplicative effect with diversity, whereby bird species with high reservoir competence are both preferred by mosquitoes and more likely to be abundant in low-diversity communities. In other words, the effect of feeding preferences compounds the effect of bird diversity. This interpretation reinforces the notion ([Ostfeld and Keesing, 2000a](#); [Ostfeld and LoGiudice, 2003](#); [Schmidt and Ostfeld, 2001](#)) that the nonrandom sequence by which species are lost as biodiversity declines is critical in understanding the relationship between biodiversity and disease risk.

Hantavirus Pulmonary Syndrome

The hantaviruses (family *Bunyaviridae*) appear to be common rodent-associated (or occasionally insectivore-associated) viruses that are widespread in Europe, Asia, North America, and South America. They appear to be nonpathogenic in their small-mammal hosts ([Yates et al., 2002](#)), although more research is required to substantiate this. Virus particles can be shed at a high rate in the first few weeks after infection in the host's feces, urine, and saliva, after which the host's immune system often substantially reduces or eliminates viremia. Virus

is transmitted among individual small mammals during contacts such as biting, scratching, licking, and grooming. Cohabiting a burrow or nest with an infectious animal might also result in transmission to uninfected individuals. Humans can be exposed to hantaviruses if they inhale airborne particles of small-mammal excreta that contain virus particles. Such events appear to be uncommon and possible only when people dwell in heavily rodent-infested closed spaces such as cabins, sheds, or homes (Yates *et al.*, 2002). Although human diseases caused by hantaviruses are rare worldwide, they can be quite devastating. For instance, hantavirus pulmonary syndrome, which occurs in the Americas, has a case fatality rate of about 30% (Yates *et al.*, 2002), which is among the highest of any infectious disease.

Different types of hantavirus, usually named after the geographic location where they were first described, tend to attack different tissues in the human host. In Asia and Europe, hantavirus disease usually involves the kidneys or peripheral circulatory system, whereas in the Americas, the hantaviruses tend to cause pulmonary (lung) disease. Each type ("species") of hantavirus tends to be associated with only one species, or a group of closely related species, of reservoir host, although spillover to other species is possible. The list of rodent species that act as key reservoir hosts worldwide includes: the Norway rat (*R. norvegicus*), the black rat (*R. rattus*), the meadow vole (*Microtus pennsylvanicus*), the bank vole (*Myodes glareolus*), the deer mouse (*Peromyscus maniculatus*), the white-footed mouse (*Pe. leucopus*), the hispid cotton rat (*Sigmodon hispidus*), the rice rat (*Oryzomys palustris*), and the small vesper mouse (*Calomys laucha*). It is noteworthy that each of these species is a habitat generalist, geographically widespread, locally highly abundant, and resilient to anthropogenic disturbance. Consequently, these reservoir species tend to occur and even thrive in low-diversity animal communities, potentially leading to higher transmission risk when biodiversity is low.

This observation led Ostfeld and Keesing (2000a) to ask whether the dilution effect (higher disease transmission when

diversity is low) operates in the hantavirus system. Ostfeld and Keesing analyzed the data published by Mills *et al.* (1998), who surveyed Sin Nombre hantavirus infection prevalence in deer mouse populations in nine national parks scattered throughout the USA. Mills and colleagues also surveyed small-mammal biodiversity in those parks. A negative correlation between small-mammal diversity and deer mouse infection prevalence would support a dilution effect. Although the relationship between these two variables appeared to be negative, the correlation was not statistically significant (Ostfeld and Keesing, 2000a). Later, Calisher *et al.* (2002) compared infection prevalence in deer mice and small-mammal biodiversity in three sites in Colorado. In one site, where hantavirus prevalence was 13%, only two species of small mammal were trapped. In a second site, where hantavirus prevalence was 9%, four small-mammal species occurred. In the third site, hantavirus prevalence was only 2% and 19 species of small mammals were present. More recently, Dizney and Ruedas (2009) asked whether mammalian diversity and hantavirus infection prevalence in deer mice were correlated in a set of five field sites around Portland, OR. Captures of about 5000 individuals of 21 species of small and medium-sized mammals demonstrated that the sites varied dramatically in their biodiversity. Dizney and Ruedas found strong support for the dilution effect. All sites that maintained moderate to high mammalian diversity were characterized by low (approximately 2%) hantavirus infection prevalence in deer mice, whereas the one site with low mammalian diversity had 14% infection prevalence in deer mice, a result that was highly statistically significant (Figure 5). In Montana, Carver *et al.* (2011) examined the relationship between prevalence of Sin Nombre hantavirus infection in deer mice and the presence and abundance of other rodents (voles) that are not hosts for this virus. They analyzed 15 years of live-trapping data on three field plots on which deer mice were always present but voles were only occasionally trapped. They found that the presence of voles was associated, on average, with an

Figure 5 Prevalence of Sin Nombre hantavirus infection in populations of deer mice (*Peromyscus maniculatus*) as a function of mammal species diversity at sites in Oregon. Reprinted from Dizney LJ and Ruedas LA (2009) Increased host species diversity and decreased prevalence of Sin Nombre virus. *Emerging Infectious Diseases* 15: 1012–1018. doi: DOI 10.3201/eid1507.081083, with permission from CDC.

extraordinary 54–64% reduction in infection prevalence of deer mice. Deer mouse infection prevalence did not vary with vole population density; the mere presence of voles, even in low numbers, apparently was sufficient to suppress mouse infection rates. On the Channel Islands of southern California, Orrock *et al.* (2011) found that the species diversity of predators on small mammals (carnivores and raptors) was a highly significant predictor of hantavirus infection prevalence in deer mice.

Studying a European hantavirus (Puumala virus) in northern Belgium, Tersago *et al.* (2008) asked what factors might contribute to variation in infection prevalence in the reservoir host, the bank vole. Studying 14 sites over 2 years, Tersago and colleagues found that hantavirus infection prevalence varied from 0% to 16%, with vole populations at <20 individual per hectare having no detectable hantavirus. Where hantavirus was present, infection prevalence in bank voles was strongly, negatively correlated with the relative abundance of a nonreservoir host, the wood mouse (*Apodemus sylvaticus*), which was the only other common rodent at these sites. Once again, these results strongly support a dilution effect. Piudo *et al.* (2011) assessed the causes of variation in infection prevalence of an Argentine hantavirus, Andes virus, in its reservoir host, *Oligoryzomys longicaudatus* in both peridomestic and forest habitats of Patagonia. They found that *Ol. longicaudatus* was the numerically dominant small-mammal species in peridomestic habitats with low diversity but not in “sylvan” ones, supporting a major tenet of the dilution effect (that principal reservoirs tend to predominate in disturbed, low diversity habitats). Piudo and colleagues found that the number of infected *Ol. longicaudatus* was negatively correlated with small-mammal diversity during the same month and in the prior 2 months; however, they did not find a significant correlation between mammal diversity and infection prevalence in the reservoir host.

In all of the above-described studies of the relationship between biodiversity and hantavirus infection prevalence, the study design was correlational and no experimental manipulations were imposed. Cause and effect relationships can be postulated but rarely rigorously tested with such study designs, and mechanisms that underlie the putative causes of reduced infection prevalence are difficult to elucidate. But substantial progress has been made in understanding the mechanisms underlying the dilution effect in hantaviruses. The Disney and Ruedas (2009) study did not find that higher mammalian diversity was associated with lower abundance of deer mouse reservoirs, nor that hantavirus infection prevalence was positively correlated with deer mouse abundance. They therefore conclude that the “susceptible host regulation” mechanism was not supported but that the “encounter reduction” mechanism was supported (see Figure 1). Studying hantavirus dynamics in Utah, Clay *et al.* (2009b, c) and Lehmer *et al.* (2008) found a somewhat more complex set of relationships to be influencing infection prevalence in deer mice. Among 16 large field sites, Clay and colleagues found a negative correlation between nocturnal mammal diversity and infection prevalence of deer mice with Sin Nombre virus, supporting the dilution effect. They found that both the population density of deer mice and the average survival (persistence) of individual mice were lower where diversity was higher. But infection

prevalence was negatively correlated only with deer mouse survival and not with deer mouse density (Clay *et al.*, 2009a, d; Lehmer *et al.*, 2008). When they monitored encounter rates and durations between mice in foraging plots, Clay *et al.* (2009d) found that high mammalian diversity was significantly correlated with reduced frequency of encounters between mice, supporting the encounter reduction mechanism of Keesing *et al.* (2006). The weight of evidence for the hantavirus pulmonary syndrome system in western North America suggests that high diversity of mammals causes deer mice to increase their frequency of encounter with heterospecifics at the cost of encounters with conspecifics. Heterospecific (interspecific) encounters typically do not result in hantavirus transmission, whereas hantavirus transmission rates correlate positively with the frequency of intraspecific encounters.

The role of biodiversity in the transmission dynamics of hantaviruses was recently studied experimentally by Suzan *et al.* (2009) in the Azuero Peninsula of southwestern Panama, where an outbreak of hantavirus pulmonary syndrome killed >20% of the ca 50 human victims (Ruedas *et al.*, 2004). Two hantaviruses had been described in this region, Choclo virus and Calabazo virus, although only the former is known to be pathogenic in humans. The natural reservoirs of Choclo and Calabazo virus are, respectively, the pigmy rice rat (*Oligoryzomys fulvescens*) and the cane mouse (*Zygodontomys brevicauda*) (Ruedas *et al.*, 2004). Suzan and colleagues established 24 study sites in patches of tropical forest in the vicinity of the outbreak of human cases. In all sites they established live-trapping grids to assess the abundance and diversity of all small mammals present, using standard mark-recapture techniques. They designated 16 of the sites as “removal” plots, from which they permanently removed all species except pigmy rice rats and cane mice; rice rats and cane mice were marked and released after drawing a blood sample, but were otherwise unmanipulated. On the remaining eight sites – the control sites – the investigators marked and released all animals captures. This design was intended to experimentally reduce small-mammal diversity according to patterns observed in nature, in which diverse communities contain rice rats, cane mice, and many other species of rodents and small marsupials, and species-poor communities contain rice rats, cane mice, and few other species (Ruedas *et al.*, 2004; Suzan *et al.*, 2008a, b). In the 16 experimental plots from which nonreservoir species were removed, two dramatic effects were observed. First, population densities of the two reservoir species were significantly increased relative to their densities on the control plots (where no removals took place). Second, the removal of nonreservoir species was associated with a dramatic increase in the proportion of the reservoir populations that was infected with hantavirus. In the control plots, about 8–12% of rice rats and cane mice were infected, whereas on the plots from which nonreservoirs were removed, infection prevalences of rice rats and cane mice were about three times higher, about 35%. Thus, this experimental manipulation of diversity supports two mechanisms underlying the dilution effect. The increased population density of reservoir species where other species were removed suggests that high mammalian diversity regulates the abundance of reservoir hosts. And the increased infection prevalence in reservoir populations suggests that high diversity reduces encounter rates

between susceptible and infected members of the reservoir populations that can result in transmission.

Schistosomiasis

Schistosomiasis is a parasitic disease caused by a trematode (flake) that uses freshwater snails as an intermediate host and a vertebrate as a definitive host (defined as the host in which sexual reproduction takes place). The disease is endemic to 74 countries and affects more than 200 million people worldwide, almost exclusively in tropical and subtropical countries (Committee, 2002). Infected humans release schistosome eggs when they urinate or defecate near freshwater sources, and these eggs hatch into a free-swimming form called miracidia. Miracidia orient toward freshwater snails, burrowing in through the snail's foot, and once inside this intermediate host they replicate rapidly, producing thousands of new parasitic forms called cercariae. Infected snails release dozens of cercariae each day, and these cercariae swim about seeking a suitable vertebrate host. The trematode that causes most schistosomiasis cases in humans, *Schistosoma mansoni*, uses snails in the genus *Biomphalaria* as the intermediate host. *Biomphalaria* snails can coexist with other species of freshwater snails and these snails can attract schistosome miracidia, but non-*Biomphalaria* snails tend not to become infected and in fact can regulate miracidia by consuming them.

Johnson *et al.* (2009) conducted an experimental laboratory study to test whether increased diversity of snail species reduced human risk of exposure to schistosomiasis. Using 200 experimental containers, Johnson and colleagues housed *Biomphalaria glabrata* snails either alone or together with other snail species that do not support replication by miracidia. The numbers of *Bi. glabrata* snails was held constant among containers, some of which also contained either *Helisoma trivolvis* or *Lymnaea stagnalis* snails, or both. After adding known concentrations of *Sc. mansoni* miracidia to the containers, Johnson and colleagues monitored the proportion of snails infected and the numbers of cercariae released by the snails, both in total and per snail. Cercarial release rates are strong predictors of human risk. In containers with two or three species of snail (*Biomphalaria* plus one or both of the other snails), both the proportion of snails infected and the cercarial release rates were strongly reduced as compared to low diversity containers containing *Biomphalaria* alone. *Biomphalaria* snails raised alone released, on average, between two and five times as many schistosome cercariae as did the snails raised together with one or two other species (Figure 6). The mechanism by which *Helisoma* and *Lymnaea* snails reduced disease risk was the deflection of miracidia away from *Biomphalaria*, in which they replicate rapidly, to these other snail hosts, which act as dead ends. Thus, high snail diversity reduces disease risk via the encounter reduction mechanism.

Global Scale Patterns of Diversity and Human Infectious Diseases

The previous section, Biodiversity and Infectious Disease, describes theory and data that demonstrate a negative effect of

Figure 6 The rate of release of infective stages of *Schistosoma mansoni* parasites by their main intermediate hosts, *Biomphalaria* snails. *Biomphalaria* snails were raised either alone or together with one or two other snail species. Increased diversity of snails strongly reduced the release of infective cercariae. Reprinted from Johnson PTJ, Lund PJ, Hartson RB, and Yoshino TP (2009) Community diversity reduces *Schistosoma mansoni* transmission, host pathology and human infection risk. *Proceedings of the Royal Society B-Biological Sciences* 276: 1657–1663. doi: DOI 10.1098/rspb.2008.1718, with permission from Royal Society of Publishing.

high biodiversity on the transmission of infectious agents and therefore risk or incidence of infectious disease. An alternative perspective has recently been explored by researchers asking whether global patterns of human infectious diseases are positively correlated with global patterns of biodiversity. One of the best-established patterns in the field of ecology is the latitudinal gradient in species diversity, such that for most taxa, more species occur in low-latitude areas than in higher-latitude areas of similar size (Pianka, 1966). Recently, researchers have asked whether this same pattern pertains to parasites and pathogens of humans. It is plausible that the greater the diversity of human pathogens, the greater the burden of disease. Moreover, because many infectious agents of humans are or were zoonotic, it is possible that disease risk will be higher where vertebrate biodiversity (representing the sources of zoonotic pathogens) is higher. We might therefore expect a higher burden of infectious disease in the tropics, where pathogen and zoonotic host diversity are higher, than at higher latitudes. Such hypotheses provide an apparent contrast to the dilution effect, because they emphasize the possibility of a positive correlation between diversity and disease risk.

Recently, Guernier *et al.* (2004) argued that, like their free-living counterparts, parasitic and infectious agents of humans also exhibit their highest levels of diversity at low latitudes. Many of the species present at low latitudes also occur at higher latitudes, with relatively few species occurring only at higher latitudes, leading to a geographically nested pattern of these infectious agents. The same general pattern pertained to

viral, bacterial, fungal, protozoal, and helminthic pathogens. Guernier and colleagues postulated that the latitudinal gradient in pathogen species richness was caused by a gradient in the maximum range in precipitation, rather than by total precipitation or average temperature. The question remains, however, whether human disease risk is higher where the diversity of potential pathogens is higher.

Dunn *et al.* (2010) addressed this question by regressing the prevalence of human diseases caused by helminths, protozoal parasites, and two bacterial pathogens (22 diseases in total, with prevalence categorized as endemic, sporadic, or nonendemic) in various political units against the species richness of viral, bacterial, protozoan, and helminthic pathogens (347 pathogens in total) in similar political units. The disparate taxonomies and sample sizes used in the two variables were a consequence of data availability. They found a positive relationship between disease prevalence and pathogen species richness. Dunn and colleagues further found a positive association between total pathogen species richness and the species richness of birds and mammals, which act as zoonotic hosts. Using structural equation modeling, Dunn and colleagues concluded that bird and mammal species richness drives richness of human pathogens, which in turn drives the prevalence of the 22 diseases in their database.

In contrast, Jones *et al.* (2008) compiled a dataset consisting of 335 infectious diseases of humans having emerged after 1940, and found that, "The highest concentration of emerging infectious disease (EID) events per million square kilometres of land was found between 30 and 60 degrees north and between 30 and 40 degrees south, with the main hotspots in the northeastern United States, western Europe, Japan and south-eastern Australia." (Jones *et al.*, 2008, p. 991). In other words, emergence of infectious human diseases is concentrated in the temperate zone and not in the tropics. Jones and colleagues

were concerned that the geographic pattern of EIDs could be biased by geographic variation in the abundance or activity of scientists likely to detect and report these diseases. They attempted to account statistically for this suspected "reporting bias" by including as an independent variable in their spatial analyses the frequency of each country listed as the address for each author in all papers published in the *Journal of Infectious Diseases* since 1973. When they accounted for reporting bias in this fashion, Jones and colleagues found that the emergence of drug-resistant pathogens and all zoonotic pathogens from nonwildlife remained more likely at higher than lower latitudes, whereas emergence of zoonotic pathogens from wildlife and vector-borne pathogens were not significantly associated with latitude. Jones and colleagues found that wildlife species richness was significantly, positively correlated with emergence events of zoonotic pathogens from wildlife hosts, but their analysis indicated that the effect was very weak (odds ratio of 1.01, or a 1% increase in emergence probability over the range of species richness) (Figure 7).

From these studies, it is difficult to draw strong conclusions about geographic associations between wildlife species richness, species richness of human pathogens, and either the probability of disease emergence or prevalence of human disease. A positive relationship between wildlife species richness and species richness of zoonotic pathogens seems well supported, but whether higher pathogen richness leads to greater incidence of human diseases – emerging or established – is not yet resolved. Poor resolution might be partly due to the disease data used in these analyses. The variables used range from crude categories of prevalence (endemic, sporadic, or nonendemic) to counting instances of emergence. Owing to data limitations, more relevant quantitative data on incidence rates (cases per capita per unit time) or risk (probability of exposure as represented by abundance of infected hosts or

Figure 7 Number of emerging infectious disease events compiled by Jones *et al.* (2008), with size of circle proportional to the number of events. See Jones and colleagues for details on how EID events are defined and located.

vectors) are not available at these broad geographic scales. Similarly, biodiversity data are often crude and perhaps inappropriate for some analyses. Diversity data typically consist of counts of species (species richness), rather than containing information on evenness or species composition. Moreover, they are generally obtained by superimposing various species' range maps, which account for species presence or absence at extremely coarse scales, over political units in which disease data occur over quite different scales.

A critical source of confusion in the literature on diversity-disease relationships is the existence of variable metrics of both diversity and disease. As argued above from both theoretical and empirical bases, species richness alone is expected to contain relatively little information of use in predicting pathogen transmission (Ostfeld and Keesing, 2000a; Schmidt and Ostfeld, 2001). Metrics that include species richness and evenness provide more information, but the changes in species composition that accompany changes in richness and evenness are required in many cases to understand impacts on pathogen transmission (Keesing *et al.*, 2006, 2010). Similarly, counts of emergence events provide relatively little information on the true burden of infectious disease. More information is contained in crude prevalence metrics such as endemic or sporadic disease. But ecological risk (the abundance of infected hosts or vectors) is a more precise metric of the probability of exposure, holding human behavior constant, and incidence rates are the foundation of understanding true exposure. In addition, coarse-scale geographic analyses of correlations between the size of the potential species pool representing pathogen diversity and disease emergence or prevalence do not by themselves inform biodiversity policy or management to reduce disease risk. At best, geographic gradients in pathogen diversity provide the upper bound of how many infectious diseases human populations might be expected to encounter in a given location. But these gradients do not tell us how we might expect disease risk to change when human activities change biodiversity.

Concluding Comments

Biodiversity affects human health in myriad ways and in some cases the relationship is complex. In a broad sense, human health relies fundamentally on biodiversity, because virtually all elements necessary for health, including food, medicine, shelter, and energy, require diverse life forms. To focus the discussion of biodiversity-human health interactions, it is useful to ask how *changes* in biodiversity affect *changes* in human health. Considerable information now exists to describe how various human activities are both reducing and changing the composition of biodiversity in virtually all ecosystems on earth. This essay has reviewed our knowledge of how those changes affect basic biomedical research, preventative and therapeutic agents, nutrition, and infectious disease. This knowledge is required for sound policy and management decisions that will affect future changes in biodiversity.

Strong evidence indicates that species of animals, plants, and various microbes that either currently do or potentially will contribute importantly and perhaps uniquely to basic biomedical research are threatened with extinction. Similarly,

many species with the potential to provide important medicines and foods are currently threatened, and many have probably already disappeared without documentation. To help advance policy that will maximally protect human health benefits, we need to pursue the relationship between the likelihood that species will be valuable as foods or medicines and their vulnerability to decline and extinction.

Detailed studies of several important zoonotic diseases strongly support a protective role of high biodiversity. Reduced rates of pathogen transmission and disease risk that accompany high diversity have been documented in infectious diseases of humans, wildlife, and plants (Keesing *et al.*, 2010). The generality of this pattern appears to result from the following observations: (1) different species within host communities play dramatically different roles in supporting transmission of pathogens, with some amplifying and others suppressing pathogens. Similarly, hosts can differ dramatically in how they affect survival and population dynamics of arthropod vectors of those pathogens; and (2) the host species most likely to support pathogen replication and transmission tend to be ecologically resilient species that persist or even thrive in disturbed habitats that lose biodiversity. The host species most likely to suppress pathogen transmission tend to be less resilient and therefore to disappear preferentially as human activities reduce biodiversity. The mechanisms that underlie the correlation between ecological resilience and host quality are only beginning to be assessed.

In some cases, it is plausible that biogeographic areas with high native biodiversity contain more potential sources of zoonotic pathogens, such that risk of infectious diseases emerging is higher in more diverse than in less diverse places. However, once a pathogen has emerged, the body of scientific studies suggests that transmission will be inhibited by high diversity. Moreover, if the potential sources of zoonotic pathogens tend to be the species that are resilient to anthropogenic disturbances, then the loss of biodiversity will be likely to increase the probability of emergence anywhere along a biogeographic gradient in native biodiversity.

Glossary

Afforestation Planting of previously unforested land with trees.

Agroforestry Practice of combining agricultural crops or animal husbandry with the maintenance and cultivation of trees on the same patch of land.

Deforestation Complete or almost complete removal of trees to less than 10% of tree cover and conversion of forested land to other uses as a result of human activities.

Desertification Development of desert conditions as a result of human activity, frequently by overuse of trees and overgrazing, or climate change.

Forest Land with minimum tree height of 5 m, a tree canopy cover exceeding 10%, and minimum area of 0.5 ha

Forest certification Procedure whereby an independent third party inspects forest management and timber harvesting practices to assess compliance against a set of ecological, economic and social standards for sustainable forestry.

Forest degradation Damage to forest ecosystems through human activities that does not result in the total elimination of forest cover.

Natural forest Area of land that supports a minimum of 10% tree cover that has arisen as a result of natural processes of establishment and succession.

Plantation Area of land that supports planted forest, usually for commercial exploitation.

REDD Reduced Emissions from Deforestation and forest Degradation: one form of payment for environmental service where carbon storage value of forests threatened by degradation or clearance is financially recognized through payments to forest owners (usually, but not exclusively, nation states) to conserve the forest.

Secondary forest Area of previously forested land that was subsequently degraded or deforested through human or natural action but which now supports regenerating or mature natural forest.

Shifting cultivation Temporally or spatially cyclical agricultural system that involves the clearing of land followed by cultivation and fallow periods.

Introduction

Deforestation is the complete or almost complete removal of tree cover and conversion of the land to other uses. A clear definition of deforestation is, however, challenging on account of differing definitions for forests. The UN Food and Agriculture Organization (FAO) defines forest as land with minimum tree height of 5 m, a tree canopy cover exceeding 10%, and minimum area of 0.5 ha (FAO 2009). Other definitions use 2–5 m tree heights, 10–30% canopy area, and as little as 0.01–1 ha minimum area. This article uses the FAO definition, and therefore deforestation is taken to mean the semi-permanent depletion of tree crown cover to less than 10%. Deforestation differs from forest degradation in that the latter represents significant damage to forest ecosystems but where forest cover exceeding 10% is retained.

Historical Deforestation and Land Clearance

At the advent of agriculture, approximately 8000 years ago, forests are thought to have covered approximately 40% of the world's land area, or approximately 6000 million ha. Up to AD 1500, the spread of agriculture across the globe resulted in the clearance of many forests, particularly those on the most accessible and fertile land. The areas most affected were the Middle East, the Mediterranean, South Asia, Europe, and the Far East. Despite the long history of human occupation of

Africa, evidence for early human clearance of African forests is patchy and localized, although currently uninhabited and forested regions of Congo reveal evidence of early human occupation in the form of pottery shards and charcoal in the soil. Deforestation in the New World was, however, clearly underway long before the arrival of Europeans, including indigenous large-scale landscape transformation at sites across the Amazon basin from AD 250 to approximately AD 1600.

Deforestation in temperate forest regions accelerated rapidly from late eighteenth century driven. The industrial revolution, expanding populations and increasing affluence, put tremendous pressure on the remaining forests to supply fuel for industrial development and land for agriculture, and by the end of the nineteenth century woodlands and forests across Europe, Russia, and China had been cleared. In nineteenth century North America, settlers cleared around 142 million ha of temperate forests for agriculture and a further 8 million ha for industry and urban development. This trend was paralleled by other lands colonized by Europeans, notably New Zealand and Australia.

European conquest and settlement of the Neotropics decimated indigenous communities through disease resulting in the abandonment and secondary regrowth of formerly cultivated areas of Amazonia. Settlers from Europe, however, started to clear accessible forests of coastal Brazil and the Caribbean for sugar plantations in the seventeenth and eighteenth centuries. India was heavily exploited for its teak

and for its potential to grow cash crops by the British colonial administration in the early nineteenth century, resulting in extensive forest clearance. Deforestation in coastal regions of Southeast Asia was equally extensive and driven by improved transport infrastructure and peasant immigration particularly from 1850 to 1920. The onset of industrial timber extraction after 1920 dramatically accelerated Southeast Asian deforestation, as it has elsewhere in both temperate and tropical forests. Between 1850 and 1980, 15% of the world's forests and woodlands were cleared.

Contemporary Deforestation

Deforestation and land clearance in the twentieth century increased greatly, with the highest rates of clearance occurring since 1960. Most current deforestation occurs in the tropical regions, whereas in north temperate countries there has been a net annual 0.1% increase in forest cover from 1990 to 2005 due to reforestation and regeneration policies. In China, forest cover has increased even more dramatically with a positive annual change of 1.2% through 1990–2000 and 2.2% for 2000–2005. This overall increase in temperate forest cover, however, masks inconsistencies at national scales. Thus in Canada, although deforestation is declining, with the annual

rate dropping from nearly 68,000 ha in 1990 to approximately 45,000 ha in 2008, large hydroelectric projects caused deforestation spikes in 1995 and 2006.

By 2008, global forest area shrunk to 397 million ha (Table 1), largely as a consequence of human exploitation in the latter half of the twentieth century. The total area of forest cleared globally between 1990 and 2005 is 125 million ha, approximately 3% of the 1990 forest extent. This represents a decline from the high rates of the 1980s, when annual global deforestation amounted to around 14.0 Mha, to the lower rates of 8.9 million ha annually in the 1990s (Table 1). Since 2000, global forest loss has declined further, and is estimated at 7.3 million ha annually. There are, however, large regional variations: almost all deforestation now occurs in the tropics. Indeed, since 1990 some 7.8% of tropical forest have been lost, with an equivalent amount lost in the 1980s.

Deforestation is now largely a tropical concern, and most deforestation is concentrated in relatively few tropical countries. The top 10 deforesting countries, which are all tropical or sub-tropical, account for 63% of total deforestation of all countries that show a net loss of forest area during 2000–2005 (Table 2). A large proportion of the world's biodiversity is found within tropical forests, and so tropical deforestation has considerable relevance to global biodiversity conservation (Table 3).

Table 1 Annual changes in forest area

	Forest area (2005)	Annual forest change			
		1990–2000		2000–2005

In temperate countries, and particularly Europe, there is no overall deforestation in terms of net area but rather a small increase in forest cover owing to policies of regeneration and afforestation. This, however, disguises a steady and continuing transition from natural or seminatural forest stands to plantation forests. Forest cover in Europe has consistently increased in recent years and a relatively high proportion of its land area is under forest cover. Much of this comprises planted forests or regrowth as most of the original forest cover was cleared centuries ago. Declining population, low land dependencies, concern for protection of the environment, and a well-developed policy and institutional framework all favor further expansion of forest area. The exception to this trend may be Eastern Europe and Russia, where the importance of forest resources as an accessible and tradeable commodity takes priority. This could be compounded by the projected

impacts of increasing frequency and extent of fires (due to climate change) in the Russian Federation as well as in parts of Western Europe such as the Iberian Peninsula.

Causes of Deforestation

There is no single cause of deforestation but rather it is the result of the interaction of social, economic, political, and cultural forces with the environment. Several underlying socioeconomic causes create conditions that favor forest clearance by readily identifiable direct causes.

The causes of deforestation vary among regions. In Africa, FAO reports that the major direct cause of deforestation is clearance by farmers driven by increasing population pressures. In Latin America, settlement and infrastructure projects

in forested areas result in clearance of land for cattle ranching and permanent agriculture, often combined with financial incentives in the form of subsidies and favorable tax policies. In Asia, intensive timber harvesting and shifting cultivation as well as the expansion of large-scale agricultural projects and plantation crops, such as oil palm and rubber, and to a lesser extent transmigration projects, all contribute to deforestation. Forest land is often not suitable for sustainable agricultural development, and as soils become exhausted new areas of forest have to be cleared. For example, 80% of the Amazon basin is ill suited to sedentary farming. Desertification through unsustainable agricultural development has contributed to much deforestation in drier regions of Africa and Asia.

Underlying Causes of Deforestation

The underlying causes of deforestation are the factors that give rise to conditions in which forest clearance becomes a rational or necessary behavior. They may be local or national socio-economic or political forces, or they may be external global forces such as the state of the global market economy. They are generally beyond the control of an individual but strongly influence the decisions individuals make regarding the management and use of forests and forest resources.

Population Growth and Poverty

Population growth is one of the most publicized underlying factors for tropical deforestation. Average global population growth over the past three decades has been 820 million per decade. Most of this increase occurs in developing countries in which deforestation is greatest. Increasing populations place pressure on forests by increasing demand for food, energy, water, wood, paper, and a variety of other products. The importance of population pressure as an underlying cause for deforestation can be misleading in that it is dependent on the ability of the land to support the population, the importance of forest for supplying goods and services to the people, and the level of control by national or local institutions.

An estimated 3.25 billion people (2004 figures) live in rural areas and are dependent on agriculture to meet their basic needs. The rural poor have very few economic options and are often forced to seek short-term solutions to their economic problems. These solutions include clearing forested land to grow subsistence crops. Opportunities for improving livelihoods by other means are limited due to the lack of rural capital, low capacity of subsistence farming to generate income, and the lack of infrastructure and education.

Development Policies and Tax Incentives

Debt repayments constitute a large proportion of the national budget of many tropical countries, and structural adjustment programs introduced as a result often favor the maximization of foreign exchange through direct and unsustainable exploitation of forest capital and by conversion of forests to agriculture for export crops. Large-scale extensive agricultural development, frequently at the expense of small farmers as well as forest cover, is further encouraged through the provision of state subsidies for agriculture and livestock expansion, reduction in income and corporate taxes, and tax breaks

on imports of equipment for new industries. Expansion of agricultural crops for export or to satisfy national demands destroys forest directly but also causes the displacement of subsistence farmers who are forced to relocate and clear new and often marginal lands elsewhere.

The privatization of public resources, advocated by the World Bank and other bilateral donor agencies, favors management strategies that maximize the short-term economic gain for the new owners, whereas non-monetary forest services, such as soil conservation and watershed protection, are not valued highly in a market-driven environment. Government incentives and subsidies have allowed some otherwise uneconomical industries to prosper at the expense of forest cover, whereas development projects often fail to account fully for the value of forest capital lost.

A lack of understanding of the real value of forests goods and services results in poor policies. The institutional weakness of the national forest department or corruption within the government can lead to policy decisions that favor private interests at the expense of the benefits to society as a whole. In recent years there has been an improvement in the reformulation of forest policies of several tropical countries. Subsidies that promote cattle ranching have been withdrawn in Brazil, whereas Costa Rica is now beginning to account for the destruction of forest capital in its national economy.

Resettlement Programs

Government-sponsored resettlement programs, such as the transmigration programs of Indonesia and Brazil, encourage landless farmers or the urban poor to clear areas of forest for subsistence agriculture or for the cultivation of cash crops for export. These schemes relieve the pressure of urban crowding and allow governments to avoid the difficult issue of land reform by providing new agricultural land from forest. However, many forested lands are unsuitable for permanent agriculture and resettlement programs have invariably failed as a result. Transmigrants are thus forced to resort to shifting cultivation, leading to further forest degradation and deforestation.

Tenurial Policies

Eighty-four percent of the world's forests are publicly owned, although private ownership is on the rise, whereas much of the agricultural land is owned by large land owners or corporations and is therefore not accessible to the majority of the farming population. Small farmers, who may not have legal title to their land, are frequently displaced or forced to sell their land because of increasing debts. These farmers often move to the forest frontier to clear a new plot of land, a practice that continues because it is usually easier for governments to ignore deforestation than to deal with the difficult issues of land redistribution.

Without legal land title there is little incentive to invest in the land to make it more productive, and it becomes more economically logical to pursue short-term gain and to move on to clear new forest land once productivity declines. Because most tropical forest lands are owned by the state, clearance is often illegal and governments are unwilling to grant legal title to small farmers for land acquired in this way.

Market Demands

One-third of the world's forests are primarily used for production of wood and nonwood products. As populations grow and become more affluent, the demand for forest products increases, particularly for industrial timber and pulpwood for making paper. Some countries have significant forest product exports (Table 4), though the extent to which international markets contribute to deforestation varies greatly from country to country. In the top 10 deforesting countries, national demand for forest products accounts for a significant amount of the area deforested. Furthermore, there is no strong link between increasing international demand for forest products generally and deforestation, not least because about 80% of the world's pulp and paper is produced and processed in temperate regions. Also, much of the world's industrial-grade timber is softwood (i.e., coniferous), and tropical forests are overwhelmingly broad-leaved. Supplies of industrial lumber in tropical countries increasingly come from tropical plantations, notably pines, cypress, eucalyptus, and teak.

Deforestation can be driven by growth in both the domestic and export markets. Rising production of beef in Central and South America to feed a growing domestic market resulted in extensive deforestation by ranchers, farmers, and land speculators since the 1980s. Over the past two decades the growing international demand for palm oil led to the widespread establishment of oil palm plantations in Indonesia, with palm oil exports rising from approximately 50% of production in the mid 1980s to 75% in 2006. Although the importance of export markets should not be underestimated, national market forces can be as important as international trade in determining the rates and extent of tropical deforestation. Consequently, it is likely that international trade offers only limited scope for reducing deforestation rates in most tropical countries.

Clearance of forest for agricultural production also appears to be driven by increasing national demand for agricultural crops. Self-sufficiency in agricultural production has been a primary developmental goal of many of these countries and has led to policies that encourage conversion of forests to fields.

Undervaluation of Forests and Forest Products

Where logging has preceded and been the first stage in wholesale land clearance, it is often because the value placed on the timber is no more than the cost of extraction and marketing. In this sense, logging is not only unsustainable forest management but also becomes a mining activity in which timber value reflects the ease or otherwise of obtaining the raw material. The value does not reflect cost of replacement or cost of growing beyond what is often a nominal payment of royalty to the owner. If timber was valued to reflect its true cost of replacement, then growing trees to produce timber would become economically worthwhile and hence potentially a sustainable option. Although it is not worthwhile, deforestation, especially in the tropics, is likely to continue because clearance and conversion is perceived as more profitable.

The nontimber benefits and services that trees and forests provide are often more important than their timber products. Environmental benefits, including soil protection, shelter, microclimate amelioration, contribution to regional and global hydrological and carbon cycles, are rarely quantified and hardly ever incorporated in economic assessments. Only when massive downstream flooding is traced back to wanton deforestation in the catchment are such connections made.

Thus a major underlying cause of deforestation is the widespread failure to value sufficiently both forest products and the many environmental benefits forests bring. Regrettably, this is largely because simple and widely accepted approaches to such valuations in economic terms do not exist. For example, stumpage, that is the charges that governments demand from loggers for state-owned timber, often undervalues the resource, which encourages waste and makes other land uses more economically attractive.

Weak Government Institutions

Although almost all countries have explicit forest laws and policies designed to conserve forests, laws, regulations, and policies in producer countries are poor in most areas. Some countries, such as Brazil, have implemented a major overhaul

Table 4 The importance of exports to the forest-based economies of the top 10 deforesting countries (2005)^a

of policies and regulations in recent years, though ambiguity in forest legislation remains a common problem across tropical countries. Poor enforcement of forest legislation, through lack of political will, incoherence of the forest laws, or limited capacity, ensures that many of the laws that do exist are routinely flouted.

Extensive forests by their very geography are likely to be remote from towns and cities and hence far from the rule of law. It is therefore easy for illegal logging and clearance to continue unseen and unchecked. Furthermore, forest services are frequently the “Cinderella” organization of government, being viewed as inferior to agriculture and even wildlife and tourism. Few resources are attracted, and poorly paid staff often have difficulty in ensuring that sustainable management practices are implemented and in imposing their authority on perhaps large private sector interests. Quite apart from the risk of corruption that these circumstances afford, many staff once trained simply dislike the remoteness of forest management and supervision and prefer the white-collar work of the city office.

Direct Causes of Deforestation

Various forms of agricultural development have been the main drivers of deforestation (Table 5). Agricultural expansion into forests can take many forms, ranging from haphazard subsistence agriculture at the forest frontier to large-scale and well organized cash crop expansion. Other direct causes of forest destruction, such as fire, are often simply the tools by which land clearance for agriculture is achieved. Aside from agricultural, mining and unsustainable timber extraction account for a considerable area of forest clearance. All these direct drivers of deforestation are principally relevant in the tropics.

Shifting Cultivation

The contribution of small-scale shifting agriculture to tropical deforestation remains unresolved due to the widely variable agricultural practices that are encompassed by this term. Indeed, estimates of the number of shifting cultivators worldwide vary from as little as 40 million to as high as 500 million. Some types of small-scale agriculture undoubtedly cause deforestation, but the inherent stability and long-term viability of many shifting cultivation systems are unlikely to result in long-term forest clearance. The least destructive form of shifting cultivation is when land cultivated for two or three

years is then left for a long fallow period. This long fallow shifting cultivation occurs only under conditions of very low population density. Expanding populations and land scarcity have led to more intensive farming systems and shorter fallow periods. Government policies have also created ‘shifted’ cultivators who are the typical slash-and-burn farmers of recent decades. Unlike the traditional farmers who have practiced shifting cultivation for decades, these shifted agriculturists have been forced by circumstances to cultivate habitats that are unfamiliar to them. Government resettlement and transmigration schemes attract migrants for whom forest cultivation is an unfamiliar means of generating a livelihood and income. In the Amazon, migrant cultivators are attracted to the forest frontier, where they clear and cultivate land for a few years. This land quickly becomes exhausted due to unsuitable soils or farming techniques and the land is sold to cattle ranchers and the “farmers” move on to clear more land.

Commercial Agriculture

Large-scale commercial agriculture is most frequently practiced by large corporations or state enterprises. These large operations can dispossess local land owners and farmers of the best and most fertile agricultural land, indirectly leading to deforestation in areas in which the farmers relocate. The establishment of oil palm plantations in valleys of Honduras in the 1970s, for example, displaced thousands of farmers who were forced to clear forests from steep slopes to establish new farms.

Commercial agriculture often leads to direct conversion of large tracts of forest to plantation estates and rice fields. This has been particularly prevalent in Indonesia and other regions of Southeast Asia where oil palm, coconut, or rubber plantations have been established on cleared forest land. In Indonesia, harvested oil palm plantations increased from approximately 300,000 ha in 1980 to 2 million ha in 2000 and to 5 million ha in 2008. Land clearance for agricultural development is often subsidized by governments, and because the owners of the agribusiness companies are politically well appointed there is little interest in forest protection. Areas for conversion are frequently burnt because this is the least expensive method of clearance. Climatic events such as the 1997–1998 El Niño in Southeast Asia and the 2005 Amazonian drought (caused by an increase in the North Atlantic sea surface temperatures) are used as opportunities to

burn forests, often illegally, though many such forests would already have been subjected to prior degradation.

Cattle Ranching and Livestock Grazing

Intensive clearing of forest land in South and Central America occurred as a result of the expansion of cattle ranching, which was economically attractive due to relatively low risk, little labor, well-established markets, and the availability of various government subsidies. Cattle ranching expanded greatly initially in response to the opening of large markets in North America but has been sustained by the development of the domestic markets for beef. In Colombia, the area of cleared forest lands used for grazing was 4.9 million ha at the end of 1800 and expanded to 23.8 million ha by 2000. In Central America the area of pasture is estimated to have increased from 3.9 million ha in 1955 to 13.4 million ha in 1995, largely at the expense of the region's tropical forests. Ranchers cleared forest land by purchasing it directly and employing laborers to clear the forest cover or by purchasing land or dispossessing it from slash-and-burn farmers that was then converted to grasslands. The shifting cultivators would move deeper into the forest to repeat the cycle. Thus, deforestation in Latin America due to ranching is also associated with slash-and-burn agriculture and land speculation.

Livestock grazing can be a serious cause of deforestation in Africa where livestock herds exceed the carrying capacity of the area. Such pressure is acute in the drier tropics such as the Sahel region of Africa and in the Middle East, where large flocks of sheep and goats are maintained. The history of deforestation around the Mediterranean is linked to grazing regimes, especially by goats, but past simplistic assumptions have given way to the recognition that climatic, sociological, and agrarian factors have also contributed to forest clearance.

Infrastructural Development and Industrial Projects

During the 1970s and early 1980s, development of the Amazon, largely illustrative of similar strategies throughout the tropics, was actively encouraged by the Brazilian government through the building of roads, tax incentives and subsidies, massive resettlement programs, and large-scale development programs. The Trans-Amazonian highway opened up millions of square kilometers of previously inaccessible forest to colonization and allowed further expansion of the cattle industry. Such roads improve access to poorly developed areas and therefore tend to increase the adjacent land value for nonforest uses and encourage land speculation and deforestation.

Logging roads in Asia also facilitate deforestation by allowing access to illegal loggers who might deforest an area that is otherwise merely degraded through selective logging.

Mining and oil exploration had widely publicized deforestation impacts. Large mines consume large amounts of wood for fuel, whereas oil companies clear forests to create lines for exploration, which are later used by colonizers following the exploration teams. Other large-scale development projects include hydroelectric power plants, whose reservoirs flood forests and transmission line paths are cut through the forest causing permanent loss of forest cover.

Crop and Tree Plantations

Much forest has been cleared for commercial plantation crops such as rubber, oil palm, and the crops of cocoa, coffee, and tea. Demand for land for agriculture and plantations continues to grow, fueled by the expanding human population and increasing affluence. To some extent, current climate mitigation policies have contributed to the problem by promoting the expansion of biofuels, which further increases demand for land. Increasing affluence has created a higher demand for meat and dairy products, which is often met by the conversion of forests to pasture or for the production of animal feedstocks.

Conversion of natural forest to tree plantations has also occurred, although currently such practice is deprecated and is less common. Indeed, a key principle of good forest stewardship is that forest plantations are only located on already cut-over, abandoned, or wasteland and in this way can actually help deflect pressure away from natural forest. Illustrative examples of significant conversion of natural forest formations to forest plantations include the following: conversion to exotic pines, *Gmelina*, and eucalypts at Jari in the drier east Amazon for pulp and paper production, conversion on the hills around Bulolo in Papua New Guinea – albeit with the species of *Araucaria* native to the area – for high-quality softwood veneer logs for making plywood, and clearance of miombo and savanna woodland for pine plantations in Zambia for industrial constructional material.

Fuelwood Collection and Charcoal Production

Fuelwood accounts for approximately 80% of all wood use in developing countries. Dependence on fuelwood is expected to decrease gradually with the introduction of electricity, kerosene, and propane, but to continue well into the twenty-first century. Fuelwood collection as an agent of deforestation is particularly marked near urban centers and in villages in which continuous collection results in the gradual degradation and eventual deforestation of accessible areas. This is critical in the dry tropics, along with domestic use of wood for other uses such as construction and fencing material.

Logging

Logging affects a substantial proportion of the world's tropical forests (Table 6). Most tropical logging consists of short-term exploitation of timber products with little or no concern for the future potential of the forest to provide additional resources and revenues. Indeed, estimates for developing countries in 2000 showed that only 123 million ha, or 6% of the total forest area, was covered by "a formal, nationally approved forest management plan covering a period of at least five years", in contrast to developed countries where the equivalent figure is 89% (FAO 2001). This is due to the insecurity of tenure and short concession periods, as well as poor governance, corruption and lack of capacity to enforce forest laws. The length of concessions is very often short term, sometimes less than 10 years, and in the absence of a long-term commitment, logging companies have little incentive to invest in long-term forest management. Concessions are also granted for timber with little regard for the other resources provided by the forest and the impact of the logging on local people.

Although the intensity of logging in the tropics is usually low, removal of only 10% of the timber trees can result in

Table 6 Approximate geographic extent of contemporary forest cover, deforestation, and selective logging by region in the humid tropical forest biome. Values are in km², with percentage of biome extent also given

damage to 55% or more of the remaining trees. Even so, logging operations usually result in degradation of the forest rather than its complete elimination. Deforestation does occur along logging roads, where forest is cleared for several meters on either side of the road, allowing the sun to dry the road surface. Poorly designed roads can result in severe erosion and landslides as well as facilitate movement into the area by illegal loggers, slash-and-burn cultivators and land speculators.

Illegal logging remains a substantial problem across tropical forest regions, despite estimates that from 2000 to 2010 the extent of illegal logging fell by 50 to 75% in major tropical timber producer countries. Illegal harvesting is thought to account for 35–72 % of logging in the Brazilian Amazon, 22–35 % in Cameroon, 59–65 % in Ghana, 40–61 % in Indonesia, and 14–25 % in Malaysia (Lawson and MacFaul, 2010). Worldwide, more than 100 million cubic metres of timber are illegally harvested each year, leading to the degradation and possible eventual destruction of five million hectares of forest.

Fire

Serious losses in forest cover in Southeast Asia and South America have been reported as a result of forest fires in 1997 and 1998. The causes of these fires are new large-scale commercial agricultural projects (including plantations) and shifting cultivation. The fires were exacerbated by the dry, coarse, woody debris left after logging operations and the very dry climatic conditions caused by the El Niño phenomenon. The area of forest consumed by fires in 1997 and 1998 has been estimated at more than 20 million ha (Cochrane 2003). Extensive fires in tropical moist forests have been previously associated with the El Niño phenomenon, as in 1982, but the underlying causes are clearance of forest to establish plantations of oil palm, pulpwood, and rice, and, in South America, cattle pastures and shifting cultivation.

Consequences of Deforestation

Biodiversity

Perhaps the most severe consequence of the loss of tropical forest cover is the associated loss of biodiversity. It is not

known how many species become extinct through the loss of tropical forest habitats, but estimates range up to a yearly loss of 50,000 species. Small forest fragments that often remain after clearance usually support only a small fraction of the original forest biodiversity.

Ecosystem Services

The loss or disruption of ecosystem services following deforestation is well documented, particularly for regulation of water flow through watersheds and maintenance of soil structure and fertility. Watersheds become susceptible to extremes of water flow following removal of tree cover, with which erosion of topsoil is associated. Thus, forest clearance often results in erratic water flow with periodic droughts punctuated by flood events, which put communities living downstream at risk. Loss of water purity and topsoil through erosion deprive rural communities of safe potable water and fertile soils. Tropical forest soils rapidly become marginal for farming following loss of vegetation cover due to compaction, loss of organic material, and leaching of soil nutrients. Sedimentation of coastal fisheries can deprive communities of their sources of food and income far from the sites of deforestation.

Clearance of forests disrupts these soil-conserving roles and subsequent rapid soil erosion is frequently observed, as the muddy red, yellow, and brown streams and rivers of so much of the tropics testify. Currently, over 300 million hectares of forests have been designated for soil and water conservation (FAO 2009).

Land degradation through loss or overuse of forest cover in dry forest zones can result in desertification. Firewood consumption is a significant contributing factor, but this is further compounded by overgrazing and overcultivation. The combination of these factors is resulting in widespread desertification of the Sahel in Africa, causing massive losses of topsoil and soil fertility and declines in productivity.

Global Climate Change

It is generally agreed that global climate is warming, with an increase in average global temperatures of approximately 0.3 °C each decade, due to the emissions of carbon dioxide

and other greenhouse gases from burning of fossil fuels mainly in industrialized countries. However, it is estimated that approximately 20% of total CO₂ emissions are a consequence of deforestation and forest fires as the carbon stocks in forests are liberated (IPCC 2007). The consequences of global warming are difficult to predict, but increased drought and desertification leading to crop failures and reduced productivity seem likely in many tropical regions. Higher temperature and reduced rainfall coupled with more frequent and severe El Niño events are predicted to result in increased frequency and intensity of fires in even moist low-land tropical forests. Geographic and altitudinal shifts in the distribution of vegetation types can also be expected.

Economic Losses

Annual loss of forest capital is estimated at \$45 billion (World Commission on Forests and Sustainable Development, 1999). Destruction of forest represents opportunity costs through the loss of future revenues and employment that might be derived from the sustainable management of the forest for timber and nontimber products as well as potential income from ecotourism and other such enterprises. Economic losses can be much greater if the costs of lost ecosystem services are factored into the equation. If the nontimber benefits and services tropical forests provide are even partially costed, then the value per hectare of extant forest increases enormously. This is now being quantified. For example, the previously ignored carbon sequestration role of forests now has potentially very high financial values.

Social Consequences

Deforestation leads to the loss of traditional lifestyles associated with forested regions. Individual and collective rights to forest land have frequently been ignored by developers, ranchers, transmigrants, and governments. The loss of traditional lifestyles, customs, and religious beliefs of indigenous communities in the Amazon and Borneo has paralleled the loss and degradation of forests in these regions. Approximately 200 million people in the developing world live in or at the forest margins and wholly depend on forests for their livelihoods. Rarely are their concerns heeded or their rights even acknowledged.

Prospects for the future

Agriculture

The main cause of deforestation worldwide is the expansion of agriculture in its various forms. It is estimated that over 5 billion ha of new agricultural land will be needed to sustain global demands by 2050. This more than doubles the current agricultural land area. Although much of the new agricultural land will be derived from shrublands, pastures, and the intensification of subsistence plots, it is expected that a large proportion of the new agricultural land area will be derived from the conversion of logged and degraded forest as well as intact forest.

State-supported investment in deforested marginal lands, fair credit schemes, and educational development are all needed to improve the efficiency of land use. Greater productivity from and improved use of existing agricultural land will lessen the pressure for clearance of new forested lands and will promote private investment for currently occupied land, which in turn encourages sustainable use.

Protected area systems and REDD

Efforts to reduce the rate of tropical forest loss focus on protected area systems, improving logging practices, and increasing the emphasis on the valuation of ecosystem services that forests provide. Emerging policies concerned with reducing carbon emissions from deforestation activities seek to provide financial incentives to nations and land owners to maintain forest cover. One such policy instrument is Reducing Emissions from Deforestation and Forest Degradation (REDD), which has received wide political and scientific support, but is yet to be implemented globally beyond the voluntary pilot study stage.

Protected area systems offer some measure of protection from conversion, although designation does not necessarily protect forests from encroachment. Currently, around 11% of the world's forests are designated as protected areas. To be successful, protected area systems need to be supported by adequate funding and legislation and managed by strong institutional departments. Forest protection in the tropics must often be developed with the cooperation of the local communities that use forest resources as otherwise alienation of these communities undermines adequate protection.

Logging Practices

Improved logging practices that minimize damage to forests and, which reduce the probability of subsequent degradation leading to forest loss are well-known but rarely implemented due to the perceived high cost of doing so. National standards for logging operations, where they exist, are often flouted and enforcement is weak. There has been considerable progress in recent years in legality verification, although much of this has been to minimum legal standards, which often does not include an assessment of actual harvesting practices. Certification schemes have been widely introduced to encourage producers to adopt sustainable practices, which after verification, may be certified as such with the expectation that certified products have a competitive advantage and procure higher market prices. There are several difficulties associated with certification as a means to reduce forest degradation and deforestation, the principal one being the need to ensure that certified wood is kept separate from noncertified wood from the source through the chain of custody and to the retailer. The success of certification also depends on the market demand for certified forest products, which is currently greatest in Europe. The domestic markets of timber-producing tropical countries account for the majority of tropical timber consumption in these countries, in which the market demand for certified wood remains low.

Development Projects

Neo-liberal economic policies and trade liberalization provide a system framework that promotes development of forest areas, often by large-scale infrastructure, industrial or energy generation programs. Although these create economic opportunities and have undoubted national economic benefits, they also incur substantial costs of forest destruction. The development of infrastructure, mining, urbanization, and industrialization projects is often supported by bilateral and multilateral donors, and a careful redistribution of these financial flows could benefit forests and forest peoples.

Tree Plantations

Tree and forest plantations are not substitutes for natural forest, but appropriately sited they can alleviate deforestation pressures. Plantations on already degraded land can be an excellent source of industrial-grade timber, pulpwood for paper making, and fuel – solid firewood and charcoal. Thus, they provide an alternative source of such products. Globally, forest plantations cover 140 million ha of land, about half of which is located in the tropics and subtropics.

Small-scale plantings on farms and around villages helps satisfy domestic demand for building and fencing materials, fuel, and local constructional uses. The estimated 20–30 million ha of such “woodland” further diverts pressure away from natural forest.

Profitable plantations risk undermining the perceived value of natural forest and may accelerate conversion of these to plantations. If the primary cause behind deforestation is the conversion of land for agricultural development, it is unlikely that plantations will reduce deforestation. Tree plantations do, however, offer an opportunity to reduce the pressure on natural forests if the latter are exploited primarily for wood products.

Conclusion

Deforestation is largely a tropical issue. The quality of data on deforestation rates has improved but remains poor and is the

source of contention and debate. The causes of deforestation are complex and multi-faceted, although socioeconomic factors and trade are foremost. Deforestation impacts the environment through loss of biodiversity and disruption of ecosystem processes and the economy by affecting ecosystem services and because of inefficient squandering of resources. Perhaps the most tragic consequence is the loss of traditional beliefs and customs and the displacement of forest-dependent communities. Solving the problem of deforestation requires a suite of strategies that include establishing an effective and global protected area network to preserve forest biodiversity and the genuine implementation of good practice guidelines in the use of forest resources. Ultimately, a reformulation of policy and a change in the attitudes of decision makers are needed to ensure that forests are correctly valued economically, socially, and biologically.

Glossary

Analysis, emic and etic Concepts derived from the linguistic terms “phonetics” (representing speech sounds by precise and unique symbols and by technical descriptions of articulation, as practiced by trained linguists) and “phonemics” (characterization of speech through a minimal number of symbols, typically recognized by the speakers of a language). By extension, etic refers to the external explanation of cultural knowledge and practice (such as the use of Linnean taxonomy or scientific nomenclature to describe local useful plants), whereas emic denotes the internal perspective of local people (e.g., ethnobiological categories and nomenclature).

Economic botany As originally conceived, a branch of applied botany that arose during the colonial period to identify and characterize economically important plants and the products derived from them. Currently, it is a scientific endeavor that seeks to document the properties of useful plants through agronomic, archaeological, ecological, ethnobotanical, genetic, historical, phytochemical, and other empirical approaches. It overlaps broadly with ethnobiology because both fields have witnessed a similar development in theory and methodology in recent years.

Ecosystems, anthropogenic and natural Communities of organisms and their environment formed either through human action or through natural processes. In practice, it is difficult to establish the extent to which an ecosystem is anthropogenic or natural, reflecting the current and historical impact of people on the environment.

Ethnobiology A term coined in 1935 that has been defined as the study of the reciprocal interactions between people and the biological organisms in their local environment and, recently, as the study of biological sciences as practiced in the present and the past by local people throughout the world. Many researchers consider that ethnobiology comprises numerous subfields, such as ethnobotany, ethnoecology, ethnoscience, and ethnozoology, but there is no consensus on this point.

Ethnobotany and ethnozoology Approaches to studying the reciprocal interactions between people and the plants and animals in their local environment. This definition has been criticized as broad and openended, but it captures the

common goals of analyzing traditional biological knowledge and assessing human impact on the environment. These approaches include subfields such as paleoethnobotany and paleoethnozoology, which evaluate archeological evidence on the past interactions between people, plants, and animals.

Ethnoecology Typically defined as the study of local knowledge and management of ecological interactions. Recently, some researchers have proposed an alternate definition, considering ethnoecology as an emerging field that focuses on local peoples’ perception and management of complex and coevolved relationships between the cultural, ecological, and economic components of anthropogenic and natural ecosystems. It is concerned with the interaction between knowledge, practice, and production, and it is oriented toward applied research on conservation and community development.

Ethnoscience Arose as a minor subfield of ethnography concerned with recording in great detail local peoples’ knowledge of biological organisms and the physical environment. Later, the term came to be used in a more restricted sense by cognitive and linguistic anthropologists to refer to local classificatory systems (as an object of study) and their semantic analysis (as a methodological approach). In France, the term is used to refer to ethnobiological studies in general.

Indigenous, local, and traditional Adjectives used by anthropologists, ethnobiologists, and other academics to describe people, practices, and knowledge. Indigenous denotes people (and their cultural practices and knowledge) who claim to be the original or long-term inhabitants of a particular place, in contrast to more recent colonizers. Traditional refers to established lifestyles, practices, and beliefs that guide cultural continuity and innovation – a definition that recognizes that traditions are always in a process of adaptation and change. Local, preferred by many researchers because it is the broadest and least value-laden term, indicates cultures that are found in a specific part of the world. It is commonly used to refer to people, whether long-term residents or recent arrivals (rural or urban), who make a living from the land and are knowledgeable about the biological resources in their environment.

Although the 100th anniversary of ethnobotany (coined in 1896), the golden anniversary of ethnobiology (first used in 1935), and the silver anniversary of ethnoecology (appearing in 1954) have passed, there is no consensus on the precise

definition of these fields. This is explained in part because of their relatively recent origin and the current surge in their theoretical, conceptual, and methodological refinement. Disagreement over definitions is typical of multidisciplinary

fields; in the words of Brent Berlin, ethnobiology “combines the intuitions, skills, and biases of both the anthropologist and the biologist, often in quite unequal mixtures.”

In one sense, ethnobotany, ethnobiology, and ethnoecology are new terms for old practices. People have been exploring the usefulness of diverse plants, animals, and ecosystems since the dawn of humanity. Documentation of local people's perception of the environment emerged slowly over thousands of years as scholars from many cultural traditions recorded local ways of classifying and using plants and animals. The onset of European colonization of Africa, Asia, the Pacific, and the New World gave added impetus to the study of local knowledge of tropical and temperate organisms and ecosystems.

Toward the end of the nineteenth century, academics began to use the prefix *ethno-* to refer to the way that local people view the natural world, in contrast to the perspective of natural scientists trained in universities. They coined terms such as “ethnobotany” (first used in print by Harshberger in 1896) and “ethnozoology” to describe these emerging fields of study that crossed the boundaries of natural and social sciences. Interest in traditional environmental knowledge continued apace in the early twentieth century, and in 1935 Castetter coined the term “ethnobiology,” setting as its agenda the systematic analysis of data collected by ethnobotanists and ethnozoologists to achieve a deeper understanding of local peoples' knowledge and lifestyles. Economic botany gained importance as a parallel field focused on useful plants and the products derived from them. In 1954, Harold Conklin proposed the term “ethnoecology,” originally conceived as a holistic and integrated approach to understanding local ecological knowledge and practice on their own terms, even while drawing on the concepts and methods of diverse scientific disciplines. A focus on classificatory systems and the linguistic and anthropological methods used to analyze them gave high visibility to an approach called *ethnoscience*.

In the 1980s and 1990s, further development of these various lines of research gave rise to new definitions, innovative theoretical orientations, and sophisticated qualitative and quantitative methodological approaches applied to local knowledge of the environment. In addition, ethnobiology expanded beyond its original geographical borders as the field gained importance in countries such as China, India, and Mexico. There is currently a new synthesis emerging – as yet without consensus – that defines ethnobiology as the study of biological sciences as practiced by local people throughout the world, comprising both empirical knowledge (*savoir*) and technical know-how (*savoir-faire*), and inclusive of subfields such as economic botany, ethnobotany, ethnoecology, and ethnozoology.

Historical Development of Ethnobiology

Despite the insights provided by archaeological and historical linguistic studies, setting an even approximate date of the emergence of local biological knowledge is a matter of opinion. A detailed understanding of the natural world was key to the independent emergence of plant and animal domestication over a period ranging from 8500 B.C. in southwest Asia

to 2500 B.C. in the eastern United States. However, environmental knowledge reaches even further back into history, when hunting and gathering dominated subsistence activities.

Some researchers would place the beginning of human ecological knowledge at the dawn of humanity, approximately 7 million years ago. Early human ancestors, who lived on the African continent 2.5 million years ago, apparently fashioned stone tools for harvesting and processing food, probably allowing them to adapt to new environmental conditions. It is widely assumed that humans have been observing natural phenomena, distinguishing between biological organisms and discovering their uses ever since the emergence of early *Homo sapiens* approximately 500,000 years ago. The archaeological record reveals that by 50,000 years ago, Cro-Magnons had developed technologies for construction, fishing, gathering, and hunting that were dependent on a detailed understanding of plants, animals, and other elements of the natural environment.

Just as no one knows exactly when ecological knowledge appeared on the cultural landscape, there is no clue when the original precursors of ethnobiologists came on the scene. The first critical observations of other peoples' ways of perceiving nature are probably as old as culture contact itself. Because these observations went unrecorded, the origin of the study of traditional biological knowledge is lost in history.

In the absence of other evidence, the historical roots of ethnobiology can be seen emerging over a period of several thousand years, when students of natural history from Greek, Roman, Egyptian, Chinese, Indian, Arabic, Native American, European, and other cultures began to record popular beliefs in scholarly texts. Original studies focused on medicinal botany, agriculture, and horticulture – activities that drew heavily on the knowledge of local people.

An overview of these early texts and later works reveals that ethnobiology and natural history have evolved – much like the biological species and ecosystems that are their focus – through a process of punctuated equilibrium. Certain historical periods are marked by an intensive effort to expand empirical knowledge of natural phenomena, often by incorporating local lore, whereas other epochs are characterized by an unquestioned acceptance of published works.

Early Scholars in Europe

Academics often trace their intellectual history to the era of Greek philosophers, who lived more than 2300 years before our time. This is when classical botany and zoology were brought into existence by scholars such as Aristotle, who sought to summarize all current knowledge about plants and animals in encyclopedic works. It was as part of this endeavor that scholars in Europe first made a systematic study of what local people knew about the environment. In part, Aristotle and other early naturalists such as Theophrastus – who, as author of *De Historia Plantarum* and other works, is considered the father of botany – rejected many local supernatural beliefs in their quest to understand the natural world. Simultaneously, they drew on commonsense explanations and empirical knowledge of local people when describing the classification and use of plants and animals.

Among the people who followed in the footsteps of these early naturalists is Dioscorides, a military physician born in Asia Minor in the first century A.D. He wrote *De Materia Medica*, a treatise on medicinal plants which was the standard reference of botanists, medical doctors, and other scholars in Europe for 1500 years. Apart from drawing on previous herbals, Dioscorides learned much about herbal remedies by interacting with local people he encountered during his wide-ranging travels with the Roman army in the Mediterranean region. Pliny the Elder, a Roman scholar who was one of Dioscorides' contemporaries, recorded extensive plant lore in his 37-volume encyclopedia called *Historiarum mundi* or *Natural History*. He devoted 9 volumes to medicinal plants, making frequent reference to traditional practices and knowledge.

The Doldrums of the Middle Ages

The documentation of local knowledge that marked the origin of biological thought in Greek and Roman Antiquity was much less evident in the Middle Ages in Europe. The decline of the Roman Empire virtually halted scholarly research on natural history and resulted in the destruction of much existing literature of the epoch. Throughout the Middle Ages, Europeans based their studies of medicinal plants almost entirely on the works of Theophrastus, Pliny, Dioscorides, and other early naturalists. Physicians from across the continent relied heavily on *De Materia Medica*, often trying unsuccessfully to match the local flora to the approximately 600 Mediterranean species described by Dioscorides instead of documenting the popular knowledge of their own region. As anthropologist Scott Atran (1990) summarized,

After Aristotle, the practice of copying descriptions and illustrations of living kinds from previous sources superseded actual field experience in the schools of late antiquity. Well into the Renaissance, scholastic "naturalists" took it for granted that the local flora and fauna of northern and central Europe could be fully categorized under the Mediterranean plant and animal types found in ancient works. Herbals and bestiaries of the time were far removed from any empirical base.

The Golden Age of the Moors

Despite this stagnation on the part of European scholars, general knowledge of medicinal plants was enriched by the flow of information coming from the Arab world, particularly through Spain (Andalucia), Sicily, and North Africa. Although dedicated in part to translating the works of Aristotle, Theophrastus, Dioscorides, and other classical writers, Moorish and other medieval scholars in these regions pursued empirical research that they applied to practical ends in agriculture, astronomy, botany, mathematics, medicine, and other fields. Although there are records of Arabic writings on botany dating to the ninth century, it was particularly in the twelfth and thirteenth centuries that scholars became prolific in recording precise original observations on plant and animal biology, conducting experiments on agricultural crops, and attempting to classify plants systematically. One of the key early scholars was Abû-l-Kheyr Al-Ichbili, apparently the "anonymous botanist of Seville" of the latter half of the twelfth century who

wrote the *'Umdat at-tabîb*, a botanical treatise that contains detailed descriptions of the anatomy, habitat, and local names of plants. Maimonides, a Jewish scholar resident in southern Spain during the twelfth century, contributed works such as *Book Explaining Medicinal Drugs* and *Treatise on Poisons*. The thirteenth century brought the works of Rachid-eddin Ibn Es-Sûri in the Machreq (eastern Arabic region), who is credited with the first herbal containing illustrations, which were made by a collaborating artist from both living and pressed plants. Ibn Es-Sûri traveled widely, describing formerly undocumented plants from Syria, Palestine, and Egypt that he discovered by interacting with local people of the region. His efforts were matched in the Maghreb (western Arabic region) by Abû-l-'Abbas En-Nabati – who documented local plants and their uses during his extensive travels in what is now Spain, North Africa, Syria, and Iraq – and later scholars such as his student Ibn Al-Baytar, author of the *Treatise on Simples* or *Jami' al-mufradat*, which contains information on the synonymy (including Berber and other local names), description, properties, and uses of approximately 1400 species. Throughout this period, descriptions of specific plants were drawn from multicultural sources, including Berber plant knowledge and the traditional practices of Jewish pharmacists who lived throughout Europe and North Africa, passing their profession from one generation to the next. As the Moors were forced from Andalucia and other parts of Europe, Arab science fell into decline. Later botanical treatises, including the *Hadiqat al-azhâr* of the sixteenth century Moroccan scholar and medical doctor Al-Wazir Al-Ghassani, were largely based on the *'Umdat at-tabîb* and other early works.

Scholars from Other Cultural Traditions

A similar pattern of initial empirical discovery and cross-cultural learning mixed with centuries of uncritical acceptance of written works is evident in other cultural traditions. In China, the first scholarly studies of traditional biological knowledge are thought to date at least to the fifth century B.C., approximately 200 years before early Greek philosophers began recording their ideas about botany and medicine. During this epoch, the Chinese philosopher Confucius is said to have encouraged his students to study ancient knowledge, including traditional names of plants and animals.

In the first or second century A.D., about the time that Dioscorides was afoot in the Mediterranean, Chinese scholars published the first of many *materia medica*, referred to generally as *bencao* (from a combined term for tree and grass) in Chinese, which contain information on minerals, plants, and animals used traditionally in the treatment of illness. Medical doctors of the fifth century A.D. revised these early *bencao*, providing a major reclassification of the various types of natural medicines used at the time. The resulting pharmacopoeia went unchanged and unchallenged for many centuries, much as the classic work of Dioscorides in Europe. At the end of the sixteenth century, a Chinese doctor named Li Shizhen began to emulate the practice of empirical observation that Confucius had advocated many centuries before. His major work, the *Bencao Gangmu* or *Compendium of Materia Medica*, contains information on more than 10,000 herbal remedies that he

obtained not only by studying ancient texts but also by traveling to the countryside to talk with people.

Ayurveda, a system of medicine which putatively began in India during the sixth century B.C. and spread to Sri Lanka by the third century B.C. and into Tibet by the seventh century A.D., was partially based on traditional knowledge. According to folklore, shepherds and forest dwellers familiar with the types and properties of medicinal plants first discovered the remedies used in this oriental medical practice. Their knowledge was discussed in various literary religious works called *vedas* (from the Sanskrit word for knowledge), which were apparently written in India approximately 3200 years ago, after millennia of oral transmission. Ayurvedic scholars later compiled additional empirical observations in a series of books referred to as the *Nighants*, or Vedic glossaries. During the subsequent period of foreign domination and internal conflict that brought innovation and documentation of local knowledge to a standstill, these standard texts of ayurveda remained unchanged.

Other ancient written sources that document local biological knowledge were in part the product of culture contact and changes in political and economic dominance. In the New World, for example, the Aztecs broadened their own sophisticated knowledge of medicine and agriculture as they sought tribute and learned of new useful plants from the different Mesoamerican cultures they conquered. The Aztecs cultivated many newly discovered species in extensive highland botanical gardens tended by people from various geographical regions of Mesoamerica. The depth and richness of the preconquest indigenous knowledge of the natural world are demonstrated by scholarly works, including the *Badianus Manuscript*, an illustrated herbal written in 1552 by two Aztecs who had been educated by Catholic missionaries. One author, Martin de la Cruz, was an indigenous physician who had acquired his medical knowledge empirically. The Mayas and Incas had similar literate traditions and they doubtlessly recorded some aspects of the ecological knowledge of the various ethnic groups they dominated at the height of their political power and cultural development. Many of these New World written sources of local knowledge were victims of the conquest, destroyed by overzealous missionaries and conquerors who wished to impose European culture, languages, and religion on the people of the New World.

The Renaissance and Exploration

During the sixteenth and seventeenth centuries, Renaissance botanists began to emulate the methods that Dioscorides had applied approximately 1500 years previously, bringing an end to the intellectual stagnation that characterized the Middle Ages in Europe. They carefully observed plants in the field and inquired about their local names and uses in Germany, Holland, Italy, and other parts of Europe. This experience served them well when faced with the influx of exotic species from areas of the world discovered and colonized by Europeans during this period. The diversity of biological organisms discovered by explorers stimulated Linnaeus, Darwin, and other natural scientists to formulate many of the concepts that are the building blocks of modern-day systematics and

evolutionary studies. Although Linnaeus left some notes and sketches on the use of plants by local people, his greatest contribution to the future field of ethnobiology was the incorporation of notions of folk biology and nomenclature, including the concept of morphological affinity as a criterion for defining taxa, in the scientific classification of plants.

This Renaissance was the golden age of the European herbals. The shift from manuscripts (produced by hand) to wood-cut and metal-engraved herbals published in large numbers allowed new botanical knowledge to be disseminated widely.

The quest to exploit local knowledge and economically important species which went along with colonization inspired adventurers, missionaries, and natural historians to record their observations on traditional biological knowledge in many parts of both the New World and the Old World. As ethnobotanist Richard Ford (1978) described,

A rapid progression of expeditions came to North America to discover and to colonize, and the chronicles of adventure are a record of the utilitarian value of an unfamiliar landscape and the use the indigenous people made of it. Its economic potential certainly had priority to any interest in attitudes about the land. The observations... provided the first natural history of North America and the bases for the beginning of ethnobotany.

From the sixteenth century onwards, researchers began to focus increasing attention on the biological wealth of tropical countries and the benefits it promised for Europeans. To this end, scholars drew on the knowledge of local people, who continually experiment with cultivated and managed species in anthropogenic ecosystems and wild plants harvested in natural ecosystems. Scholars consulted both written sources, such as Ayurvedic works and Chinese pharmacopoeias, and oral history to produce extensive encyclopedias of useful plants from around the world, ranging from the *Coloquios dos simples e drogas da India*, written by the Portuguese explorer Garcia ab Orta in 1563, to the 12-volume *Hortus Malabaricus* of Van Rhee de published in the late 1700s and *A Dictionary of Economic Products from the Malay Peninsula* produced in 2 volumes by Burkill in 1935.

Another notable example is the herbal of Rumphius, a seventeenth-century natural historian from Germany who spent nearly 50 years in Asia working for the Dutch East-Indies Company. Increasingly released from his administrative duties but still under the employ of the company, he focused his attention on studying useful plants, animals, and minerals in various regions that today constitute Indonesia. He provided descriptions of more than 700 medicinal or toxic plants, published posthumously in the six volumes of the *Herbarium Amboinense*.

Creation of New Fields

Although Rumphius and his counterparts approached natural history as a holistic phenomenon, scholarly activity in later centuries began to reveal a fragmentation of research into distinct disciplines, marking the beginning of reductionism in the sciences. Subdivisions of science became more clearly defined, and professional practitioners began to specialize in

specific subfields. Theoretical science was increasingly applied to technological innovation, stimulating the growth of educational institutions and commercial enterprises.

For example, pharmacognosy (the study of naturally occurring compounds that can be used medicinally and in other ways) became recognized as a separate field of endeavor in the early nineteenth century. It focused on the identification, preparation, and commercialization of drugs, which mostly came from natural sources, especially plants. This enterprise, combined with tropical exploration, yielded such novel cures as quinine, which was successfully used to control malaria in Europe and other regions.

As research on traditional biological knowledge expanded in the late nineteenth and twentieth centuries, several lines of research became apparent, reflecting the diversity of researchers who began to appreciate the importance of the subject. The historical development of these various fields is intertwined, and the definition of each is in flux. There may be an emerging consensus – one supported in this article – that ethnobiology is the broadest field, comprising ethnobotany, ethnozoology, ethnoecology, and economic botany as subfields. Other colleagues would posit ethnoecology or even ethnosience as the most inclusive term. In practice, this debate on terminology is less significant than the realization that these fields broadly overlap, and that the slight differences of opinion on definition are dwarfed by the general agreement on theory, concepts, and methods.

Ethnobotany and Related Fields

By the end of the nineteenth century, researchers began to recognize the study of traditional biological knowledge as a separate discipline. John W. Harshberger, a professor of biology, initiated the fashion of using the prefix *ethno* to indicate the study of local people's natural history. In 1896, he used the term ethnobotany in print, and it began to replace names such as "aboriginal botany" and "botanical ethnography" that had been used previously by other authors. In the words of Richard Ford (1978), after a "half century of scientific attention and an even longer history of casual observations," the study of other people's interaction with nature finally had a name and recognition as a distinct line of academic endeavor.

The emergence of ethnobotany, ethnozoology, and related fields coincided with important developments in the natural and social sciences toward the end of the nineteenth century. The diverse elements of natural history, including botany, zoology, pharmacognosy, and other fields, began to mature into distinct disciplines, each with separate methods and goals. Scott Atran (1990) characterized this as the "breakaway of science," a time when natural historians began to leave behind commonsense descriptions of natural phenomena – drawn in part from local peoples' perception and classification of nature – in order to embrace rigorous experimental methods. Social scientists began to focus on separate aspects of human society and culture, with the consequent emergence of fields such as anthropology, linguistics, and sociology.

Economic Botany

Nineteenth-century botanists, who focused primarily on the utility of plants and only secondarily on local culture, began to

refer to their approach as economic botany. The goal of their research has been to document local uses of plants and to organize the resulting data according to the global system of plant classification. They have produced detailed works on plants employed by local people for food, medicine, textiles, utensils, and many other purposes (Schultes and Raffauf, 1990).

Research on the commercial value and utility of plants expanded as botanists from the United States and Europe explored the New and Old World tropics in search of products that would increase the wealth of developed countries and the well-being of people in general. Today, economic botanists continue to search for marketable products in tropical forests and elsewhere, but they are increasingly interested in how the commercialization of these resources can contribute to resolving the poverty, malnutrition, and diminished social status of local people as well as spurring economic development in developing countries. An increasingly important offshoot of this enterprise is bioprospecting (a term derived from "biodiversity prospecting"), the search for useful and novel products (including chemical constituents of medicinal value) from plants, animals, fungi, and other biological organisms. Other economic botanists are concerned with developing theoretical and methodological approaches to understanding the subsistence and commercial value of plant resources, now and in the past.

Ethnosience

While botanists were establishing economic botany, anthropologists and other social scientists were developing a different perspective. In the tradition of ethnography developed by anthropologist Franz Boas, ethnosience emerged as a minor subfield dedicated to recording in minute detail local peoples' knowledge of biological organisms and the physical environment. The subfield underwent a further transition in the 1950s and 1960s, when cognitive and linguistic anthropologists began to focus on the empirical categories, social rules, symbolic systems, and modes of behavior that reflect how local people perceive the natural world. These early anthropological studies formed the foundations for a new ethnoscientific approach that advocated rigorous analyses of ethnobiological knowledge, with particular emphasis on systems of ethnobiological classification. Thus, whereas economic botany emerged as a utilitarian practice firmly rooted in commerce and development (and later developed theoretical frameworks), ethnosience arose as an intellectual endeavor oriented toward a deeper understanding of human culture and cognition.

Ethnoecology

Even though he is most associated with the development of the ethnoscientific approach, Conklin is credited with coining the term ethnoecology in 1954. Given the precedent set by terms such as ethnobotany and ethnozoology, it would be natural to assume that ethnoecology would refer to the study of local perceptions of ecological processes, such as nutrient cycling, vegetational succession, or the interactions between plants and animals. An increasing number of researchers propose a different definition, using the term to refer to local peoples' perception and management of the complex and

coevolved relationships between cultural, ecological, and economic components of anthropogenic and natural ecosystems. This emerging subfield, much as the broader field of ethnobiology, is concerned with the interaction between knowledge, practice, and production and is oriented toward applied research on conservation and community development. Mexican ecologist Victor Toledo stated that the aim of ethnoecology should be the ecological evaluation of the intellectual and practical activities that people carry out during their appropriation of natural resources.

Although the definition of ethnobiology includes a reference to knowledge and know-how (*savoir* and *savoir-faire*), for ethnoecologists the distinction is between an ethnobiological *corpus*, local peoples' repertoires of concepts, perceptions, and symbolic representations of nature, and *praxis*, the art, science, and skill of appropriating nature and biological resources. The interrelationship between knowledge and practice is manifested in production, as people apply their intellectual understanding of nature to the everyday tasks of farming, gathering, and hunting for subsistence and commercial purposes. In order to understand these complex interactions, ethnoecologists seek to elucidate how the management of anthropogenic and natural ecosystems – and the biological organisms they harbor – has arisen through a process of coevolution between the environment, knowledge, technology, social organization, and values of local peoples.

Although attractive conceptually, the development of this conception of ethnoecology has been limited by the lack of a unifying theoretical framework and a practical methodology. This distinguishes it from ethnobiology, which is developing a central organizing theory, an orientation toward hypothesis testing, and an increasingly elaborate set of qualitative and quantitative methods, drawn in part from ethnobotany, ethnozoology, and economic botany.

Ethnobiology

Clément (1998) proposes that the starting point for ethnobiology – as the field which integrates related approaches such as economic botany, ethnobotany, ethnozoology, and ethnosience – is the 1860s, when the first designations for the field began to be used by American and European scientists. In a historical sketch that spans a period of more than 130 years, he discusses the origins, key theories, and methodological approaches of the main trends of ethnobiology. Although no such historical framework of a scientific discipline is without controversy and potential modification, Clément's synopsis is a serious effort to provide a detailed historical analysis of ethnobiology.

Clément divides the development of the discipline into three eras and seven periods (Table 1). The preclassical period, from 1860 to 1953, is dedicated to gathering empirical data on the uses of plants and animals from an etic perspective and to the first syntheses that begin to define the scope of the discipline. During the classical period (1954–1980), there is a shift to studies carried out from an emic perspective and a particular focus on ethnobiological classification. An increase in collaborative work between academic specialists and local people and the formation of professional associations of ethnobiology characterize the postclassical period, from 1981 to the present. Later in the period, there is an increased focus

on the appropriation and management of plant and animal resources and a concern for application of research results to the resolution of environmental and social problems. This historical review provides an appropriate starting point for considering the current trends in basic and applied ethnobiological research.

Current Trends in Ethnobiology

Recent studies in ethnobiology can be classified in three general, interrelated areas. Documentation and analysis of uses of plants and animals is the oldest aspect of ethnobiology. A focus on knowledge, which became especially popular in the 1950s and 1960s, characterizes the study of perception and classification of the natural world. In the 1980s and 1990s, attention shifted to local management of biological resources and the environment, often drawing on ecological concepts and methods. These areas are combined in various degrees in the following major trends in ethnobiological research.

Cognitive Mapping

Ethnobiologists have documented local peoples' spatial conceptualization, including their ability to locate biological resources, discern landscape features, and identify different types of vegetation. This geographical literacy is linked to an aptitude for assessing the potential productivity of the environment, often through the recognition of plant species that indicate fertility or sterility of soils. This expertise derives in part from local peoples' sophisticated perception of how the various elements of the ecosystem (organisms, soils, climate, topography, etc.) form an interdependent whole. In addition, it is derived from their classification of key geographical landmarks that are labeled by specific toponyms, or geographical place names. Local views of the landscape are being integrated into geographical information systems, which in turn are useful in creating biological resource maps and management plans for specific areas. When united with ethnobiological inventories and studies of local categorization of ecological succession, community mapping allows researchers to test hypotheses on whether the highest number of useful plants and animals come from primary or secondary forest, or anthropogenic versus natural ecosystems.

Local peoples' mastery in selecting plant populations that yield the best fruit, the most potent medicine, or the best materials for construction is attributed in part to their grasp of the landscape. These mental maps also explain their adeptness at selecting the best place to cultivate the earth, create human settlements, or leave natural areas that maintain soil fertility, water purity, and other environmental benefits. Researchers have demonstrated that these skills can degenerate when local people find themselves pressured by economic needs to overexploit the resources available to them or are forced onto lands for which they are maladapted culturally.

The ability of some local people to integrate and recall complex information on the local environment often gives them special proficiency as stewards of community reserves and other protected areas. Their ability to assess the quality of

Table 1 Features of Various Historical Periods and Stages in Ethnobiology

Period	Stage	Dates	Features
Preclassic (1860–1954)	Economic uses	1860–1899	Studies of biological resources and their utility carried out by researchers affiliated with major museums and universities; general lack of appreciation of the sophistication of local knowledge and subsistence systems from an emic perspective
	Information gathering	1900–1931	Greater empirical depth in research but continued emphasis on economic uses of plants and animals; better appreciation of complexity of local knowledge and use of plants and animals, especially as reflected in systematic attempts to record local terminology, myths and beliefs, and knowledge of anatomy and behavior; emergence of comparative studies and standard methods
	The first syntheses	1932–1953	Emergence of ethnobiology as a distinct field of enquiry and appearance of the first syntheses that delimit its scope; increasing distinction between economic botany and ethnobotany, with the latter emphasizing the systematic documentation of local knowledge and management of plants; continued lack of recognition of scientific aspects of traditional biological knowledge
Classic period (1954–1980)	Emic knowledge	1954–1968	Emergence of ethnosciences, leading to a focus on the organization of knowledge systems from the local perspective, with insights from linguistics and empirical anthropological methods; relegation of the study of plant and animal resources to secondary importance; beginning of interest in ethnobiological classification and appreciation of the scientific basis of traditional knowledge
	Classification	1969–1980	Focus on ethnobiological classification, including principles of categorization and nomenclature, and the analysis of correspondence between scientific and local classifications; accumulation of evidence for the scientific basis of local biological knowledge; increasing interest in ethnobiology beyond the United States and Europe, especially in Latin America and the Pacific
Postclassic (1981 to present)	Associations	1981–1992	Production of major empirical works based on close collaboration between academic and local researchers; development of theoretical approaches beyond classification, including gender relations in resource use, cultural significance of plants, and historical reconstruction of ethnobiological knowledge systems; emergence of academic societies and specialized journals of ethnobiology, especially in developing countries
	Resource management	1993 to present	Publication of standard methods manuals, quantitative techniques, and innovative empirical studies; emergence of concern about applying ethnobiology to conservation and development; renewed interest in economic botany, including nutritional and medicinal benefits of plants, but incorporating novel theoretical and methodological approaches and informed participation by local people.

useful biological resources and to locate areas where these organisms are found in greatest density makes them indispensable members of research teams that seek to identify priority areas for conservation and management. Foresters and conservation biologists draw on this expertise when deciding how to zone natural areas according to various land-use options. Local peoples' classification of land units also plays a key role in justification for claims of ancestral domain and other forms of ownership of the lands they have long occupied.

Resource Management and Valuation

In order to ensure subsistence production and to earn a living, local people draw on their detailed ecological knowledge to manage the diverse microenvironments and biological organisms in their communities. Recent studies have shown that the process of plant domestication through selection of preferred varieties occurs not only in cultivated fields but also in other parts of the anthropogenic landscape. From the cultivation of these domesticated plants to the harvesting of wild useful species, local people engage in many ecological

practices that are often energy efficient and sustainable, at least under traditional conditions. They capitalize on the consumptive use value of natural resources when they harvest plants and hunt animals for subsistence purposes and on the productive use value when they barter or sell agricultural and forest products. They also benefit, as does the whole world, from the nonconsumptive value that comes from ensuring the viability of ecosystem function in general, including watersheds, nutrient cycles, climate, soils, and other elements.

By investigating the link between local knowledge, practices, and production, ethnobiologists assess the value of anthropogenic and natural ecosystems and the rationality of resource harvesting decisions made by small-scale farmers and gatherers of forest products. Much of this research is carried out in 1-ha plots, agricultural fields, home gardens, and other measured study sites, resulting in quantitative assessments of sustainability and value. These methods allow researchers to evaluate the hidden costs of tropical forest destruction, the economic benefits derived from both subsistence and commercial use of wild species, and the environmental advantages of maintaining forest cover as a way of buffering local climate and preserving the purity of local air, water, and soil. Through these perspectives, conservation biologists,

development specialists, and communities monitor the sustainability of current productive practices, propose new methods of managing fields and forests, and select new biological species that can be domesticated, cultivated, or gathered locally. Studies of local systems of resource management can also enrich the work of ecologists, who seek to restore the diversity and value of forest ecosystems damaged by mismanagement or natural catastrophes. In addition, evidence of long-term management of biological organisms and ecosystems reinforces local peoples' claims for traditional resource rights, including just compensation when novel biological resources are commercialized.

Scientific Covalidation

A key activity of ethnobiologists is to understand the rationale behind the way local people interact with the natural environment. In research laboratories, scientists carry out a broad array of analyses that seek to corroborate the efficacy of local uses of plants and animals, ranging from the identification of active compounds in medicinal plants to appraisal of the tensile strength of natural fibers and assessment of the nutrient content of wild foods. In the field, ecologists assess how the yields of agroecosystems compare with those achieved by large-scale monocultures and to what extent traditional methods of wildlands management are sustainable. Ethnobiologists compare ethnobiological categories with scientific taxa, judging the extent to which local biological classifications correspond to biosystematics. This range of activities is aimed at revealing the logic, from a scientific perspective, of the thought and practices of local people. Because much is understood about the classification of specific cultural domains, such as plants, animals, soil, climatic zones, and vegetation types, there is a call for ethnobiologists to study local peoples' perceptions of ecological interactions, the reciprocal relationships of various elements of the ecosystem.

Scientific covalidation allows researchers to understand how to optimize the value – and also to ensure the safety and efficacy – of plants and animals that are consumed or commercialized locally. In addition, covalidation provides insights on how traditional knowledge can be incorporated in the management of protected areas. These studies reveal the breadth of local people's ecological knowledge and the wealth of resources available in natural areas, highlighting their potential value on the world market and their contribution to local subsistence. In addition, this research plays an important role in convincing protected area managers of the value of including local people in conservation and development projects.

Ethnobiological Classification

Continuing a trend initiated by ethnoscientists in the 1950s, ethnobiologists are documenting how local people classify diverse elements of the natural environment. Based on fieldwork in diverse cultures, they describe complex interrelated sets of categories for plants, animals, soils, climates, vegetation, illnesses, food, and other cultural domains and natural phenomena.

Much attention has focused on describing universal similarities in the ways in which local people perceive the natural world. Many generalizations on the categorization, naming, and identification of plants and animals are now widely accepted, whereas others continue to provoke controversy, especially among anthropologists who place emphasis on cultural relativity or the uniqueness of each ethnic group. In particular, there is disagreement over why people are motivated to classify various elements of the environment. Some researchers seek a utilitarian explanation, suggesting that people enhance their ability to fulfill their basic subsistence needs by naming and classifying useful plants, animals, soils, and other natural features. Those who follow an intellectualist line of reasoning argue that there is a universal human tendency to categorize plants and animals according to their overall appearance or symbolic role. These researchers note that local people tend to group organisms with a similar morphology or behavior, regardless of their cultural utility. In a similar vein, some colleagues propose an ecological rationale, noting that some aspects of ethnobiological classification can be elucidated by reference to the role and interaction of plants and animals in diverse ecosystems. Although there is an emerging consensus that classification is motivated by a combination of these factors, there continues to be much debate about which is the most important dimension.

Studies of ethnobiological classification contribute to understanding – in part by reference to the global system of plant systematics – how local people perceive and manage natural resources. When carried out in a participatory way, ethnobiological inventories provide an opportunity for local people and researchers to work together to document the distribution, management, and use of biological resources locally and globally. They produce the baseline data needed to produce bilingual and bicultural manuals that compare and contrast different ways of classifying, managing, and using biological organisms. These ethnobiological manuals contribute to applied programs of conservation and development by highlighting culturally significant species that local people are harvesting from the wild, managing in anthropogenic landscapes, or cultivating in gardens and fields. Often, these species are selected for use in initiatives that promote reforestation, sustainable harvesting of minor forest products, or cultivation of useful plants that contribute to the well-being and income of local people.

Knowledge Variation

There are significant differences in the way local people perceive and use biological resources. Ethnobiological studies reveal that some plants and animals are known by a majority of the population, but others are the domain of curers, the elderly, women, or members of another social group. There are significant differences in the biological knowledge of people living in separate communities, belonging to distinct ethnic groups, speaking different languages, or subsisting in diverse ecological zones. These differences can be explained in part by the fact that each person's knowledge is correlated with sociological characteristics such as age, gender, occupation, education, social status, and zone of residence. Perception and

management of plants and animals are also affected by each individual's life experiences – for example, if he or she has suffered from a major illness, migrated to other communities, or worked as an apprentice to a plant specialist.

Awareness of these differences is essential when assessing the depth and breadth of traditional knowledge and the diversity of ecological practices in a particular area. It is now recognized that researchers run the risk of obtaining a biased perspective of local biological knowledge if they work with few informants. In contrast, consultation with a representative cross-section of local people can provide a relatively accurate portrayal of perception of the natural world. Ethnobiologists are analyzing patterns of agreement among different individuals, producing a quantitative method of identifying the most culturally significant plant and animal species, soil types, forest zones, and other elements of the landscape. These results ensure accuracy when preparing natural resource management plans and popular manuals produced with local communities. They can also play a role in understanding the knowledge held by specialist user groups and how they are transmitting it from one generation to the next.

Mechanisms of Change

Another principle that has emerged in recent studies is that knowledge about the natural environment and ways of managing biological resources are not static. They change as people move from one region to another, as youth reinterpret what they have learned from elders, and as cultures come into contact with each other. Ethnobiologists are analyzing the dynamics of these cultural changes and assessing how they can enrich or impoverish local knowledge systems.

Archaeology, linguistic reconstruction, archival research, and oral history open a window to the past, allowing researchers to discover how ecological knowledge and resource management have evolved during decades and centuries of political, demographic, and economic change. Studies of historical ecology are revealing which species, ethnobiological categories, and ecological practices have persisted, changed, or disappeared over time, including those that have become widespread through borrowing across cultural boundaries. Research that focuses on world events in recent centuries allows historians to assess the impact of colonization and other forms of culture contact on local ways of perceiving and managing the natural world.

Many regions of the world are currently in an intense period of change characterized by not only the destruction of wildlands and loss of biological diversity but also the transformation of traditional biological knowledge. In some regions, young people are not learning what their elders know about the environment, particularly as traditional ways of using biological organisms and managing natural areas fade away. Specialized knowledge held by only a few curers or spiritual leaders is lost when no apprentice is found to carry on traditional medical or religious practices. This loss of knowledge is often linked to increasing contact with national and international cultures and is often exacerbated as local people incorporate formal education, major religions, and migration into their lifestyles.

Ethnobiologists are playing a practical role in assessing the extent of cultural transformation and searching for ways of promoting the survival of local ways of classifying, using, and managing natural resources. These actions are based on the assumption that participation in the joint management of ecosystems and resources stimulates local people to retain and build on empirical knowledge and practices acquired during the tens, hundreds, or thousands of years that they and their ancestors have resided in the region. Studying the evolution of ethnobiological knowledge elucidates mechanisms of cultural resistance, allowing us to understand why local ecological knowledge persists and how we can reinforce the mechanisms of resistance. These studies also highlight the impact that local people have had on the natural environment over time, often providing evidence that they are responsible for maintaining biological diversity and stimulating innovative ideas for conservation in the future.

Ritual, Religion, and Symbolism

Plants and animals play an important role in rituals and spiritual practices and are a recurring element in myths, legends, and stories. Some researchers assert that local people, because of their cosmology or understanding of the universe, relate to the natural environment in ways fundamentally different from that found in, for example, European or American culture. A central element in this conception is that traditional lifestyles link people to nature in a way that provides them with a special understanding of nature. A common way for outsiders to gain access to the world of ritual, magic, and religion of local peoples is through apprenticeship with spiritual leaders, often accompanied by the use of psychoactive plants.

Whether or not these generalized notions of differences between global knowledge systems and traditional knowledge are valid in all cases, it is undeniable that spiritual beliefs about the forest and associated taboos on the use of natural resources are important elements of conservation and sustainable use of natural resources in many cultures. When people begin to abandon these beliefs, traditional controls on resource exploitation often disappear, potentially leading to devastation of formerly protected areas such as sacred groves. Ethnobiologists are increasingly aware of the need to record these belief systems and to verify empirically what impact they have on conservation and use of natural resources. In areas in which traditional cosmology is still a viable element of local culture, conservation biologists are exploring ways of integrating it with the management of protected areas.

The Internationalization of Ethnobiology

Although ethnobiology as an academic discipline originated in Europe and the United States, it has now been embraced by researchers in many developing countries who have subsequently adapted the techniques and concepts to their own goals and local conditions. The emergence of professional societies of ethnobotanists in developing countries, ranging from the Indian Society of Ethnobotanists in 1980 to the Asociación Mexicana de Etnobiología in 1993 and the

Sociedade Brasileira de Etnobiologia e Etnoecologia in 1997, is evidence of this trend.

The internationalization of ethnobiological research and training has resulted in new directions in theory and application, enriching the field. In India, the tradition of conducting ethnobotanical inventories in various tribal areas has continued, but it is now supplemented by innovative approaches to studying the harvest of nontimber forest products in joint forest management schemes and practical strategies to create community biodiversity registers. Researchers in China have contributed studies on ecological succession in swidden fields, marketing of useful plants, and analysis of agroforestry practices. Equally impressive are developments in Mexico, where ethnobiologists have focused on the management of anthropogenic and natural ecosystems as well as the process of domestication of botanical resources.

The New Synthesis

The proliferation of labels and orientations for the study of local biological knowledge and practice is likely to continue. Consensus on precise definitions will be difficult to achieve because researchers are approaching the field from a variety of academic disciplines, bringing with them a wealth of new concepts and methods. Despite this dynamic development, there is some semblance of an agreement on a typology for the discipline.

Distinct approaches to gathering empirical data on the reciprocal interactions between people and biological organisms will continue to be referred to by terms such as economic botany, ethnobotany, ethnoecology, and ethnozoology. Ethnobiology is becoming the preferred term for an integrative discipline that draws on all these approaches to analyze traditional biological knowledge and practices throughout the world. It is unified by a central theory that local peoples' systematic knowledge and management of biological organisms and ecosystems can be classified as biological sciences, covalidated by qualitative and quantitative research methods. Perceived in this way, ethnobiology blends conventional studies carried out by economic botanists, ethnobotanists, ethnozoologists, and ethnoscientists that present a limited vision of local people's interaction with the natural environment. This provides an opportunity for reintegration of various disciplines of natural science, counteracting the impact of the reductionism of global scientific knowledge.

Ethnobiology seeks not only to integrate these various lines of scientific research but also to focus them on supporting community development and biodiversity conservation, which are clearly multidisciplinary endeavors. American ethnobiologist Darrell Posey argued for this style of "advocacy" or "applied ethnobiology," whose goal is to reform the economic, environmental, and social policies that are at the root of many problems which affect people in rural and urban settings. This approach has stimulated a new generation of researchers to blend scientific research with an awareness of political and

ecological problems, including the loss of biotic and genetic resources, indigenous struggles for land and resource rights, and negative aspects of globalization. The ultimate goal is sustainable development, as defined by cultural, ecological, and economic parameters.

The yen for integration goes beyond creating an interdisciplinary, applied field of study. Although ethnobiologists have tended to concentrate on the empirical side of local biological knowledge, there is renewed interest in symbolic and other interpretive approaches that could give a broader view of how people perceive their natural surroundings. Many ethnobiologists advocate adopting a participatory approach through which the entire study, from research design to application of the results, is conceived as a collaborative effort between local people and researchers. These developments represent a significant achievement for ethnobiology, a field that has always sought to blend perspectives from many cultural traditions.

Glossary

Cover type A term used by the geographers for a type of mapped feature (e.g., forest, freshwater, or grassland). The dominant natural cover type in a landscape is often used to approximate habitat.

Fragmentation per se The breaking apart of habitat while keeping habitat amount constant.

Habitat The place where an organism normally lives.

Habitat fragmentation The breaking apart of habitat into several smaller pieces. Habitat fragmentation results in both habitat loss and fragmentation per se.

Habitat loss A change to an area that prevents a species from living there (e.g., conversion of forest to crop field).

Human landscape modification An umbrella term used to describe the many complex and related features and processes correlated with human-caused habitat loss and fragmentation.

Landscape complementation The degree to which a landscape provides all necessary cover types for a species that requires multiple cover types to complete its life cycle.

Matrix An area where an organism does not usually live.

Scale of effect The spatial extent over which the habitat and the matrix characteristics in the surrounding landscape influence individual, population, or community processes in a focal area.

Introduction

Habitat loss is occurring at an alarming rate. Agriculture, the major cause of habitat loss (FAO, 2010; Figure 1), covers 36% of Earth's potentially suitable land (FAO, 2003). The cover type for which loss is best documented globally is forest (Balmford *et al.*, 2002). Earth's forests underwent a net decrease of 5.2 million hectares per year between 2000 and 2010 with the greatest losses occurring in tropical and subtropical woodlands (FAO, 2010). Although some forest loss has natural causes (e.g., fire, Harrod *et al.*, 1999), most of the current forest loss results from human land use (FAO, 2010). The impact of forest loss on the biodiversity is even larger than expected from the raw number of hectares because forest loss is greatest in the species-rich regions of the tropics and subtropics (Pereira *et al.*, 2010). Furthermore, it is in these areas that the most agricultural growth is expected in the future (FAO, 2003).

Habitat loss has consistent, strong, negative effects on biodiversity. Habitat loss has negative impacts on species richness (Laurance *et al.*, 2002), population abundance (Laurance *et al.*, 2002), and genetic diversity (Aguilar *et al.*, 2008). In addition, habitat loss can shorten trophic chain length; alter species interactions; and reduce successful foraging, breeding, and dispersal (reviewed in Fahrig, 2003). A combination of agriculture and hunting is the greatest perceived threat to mammal, bird, and amphibian populations (Laurance and Useche, 2009). Habitat loss is commonly cited as the greatest threat to wild bee populations (Brown and Paxton, 2009) and is second only to hunting as the major threat to marine fish populations (Dulvy *et al.*, 2003).

Habitat loss affects not only biodiversity but also impacts humans directly by decreasing production of ecosystem goods and services such as pollination (Potts *et al.*, 2010; Ricketts *et al.*, 2008), soil and water management (Bruijnzeel, 2004), and carbon storage (Fargione *et al.*, 2008). After accounting for the potential economic benefits of habitat loss

(e.g., agricultural and mineral products), a conservative estimate of the global net economic cost of habitat loss is US\$ 250 billion per year (Balmford *et al.*, 2002).

Habitat fragmentation, or the breaking up of habitat into smaller pieces (Figure 2), is a second major effect of human land use. Its prevalence is difficult to summarize because it is confounded with habitat loss and can be measured in many different ways. Understanding of the effects of habitat loss and fragmentation on populations has been hampered by a vague conceptualization of habitat fragmentation, but some broad generalizations can be made. The strongest finding from decades of research on this topic is a consistent negative effect of habitat loss on biodiversity, although the strength of this effect depends on species traits and environmental factors.

Problems with the Concept of Habitat Fragmentation

Habitat Fragmentation is a Vague Concept Because it Encompasses Multiple Concepts

The term "habitat fragmentation" has been criticized as "broadly conceived and therefore oversimplified" (Bunnell, 1999); "a conceptually ambiguous and empirically multifaceted term" (Haila, 2002); a "catchall for human-caused habitat changes that have negative effects on biodiversity" (Fahrig, 2003); and a "generic umbrella term" that is "vague and ambiguous, thereby limiting its practical value for conservation managers" (Lindenmayer and Fischer, 2007). Despite these criticisms, the term habitat fragmentation continues to be used to refer to the general effects of human landscape modification, a practice defended by researchers who credit the term with "real heuristic value in explicit recognition of an overarching domain" (Ewers and Didham, 2007).

Habitat fragmentation refers to the subdivision of habitat into smaller pieces (Andrén, 1994; Ewers and Didham, 2006; Fahrig, 2003) and as such can refer to many potentially

Figure 1 An aerial photo depicting a typical agricultural area near Ottawa, Ontario, Canada (OMNR, 2010). To meet the growing demand for human food, forested land (shown in dark green) has been replaced by agricultural crops (usually corn, soy, wheat, or alfalfa in this region). Ontario Ministry of Natural Resources.

confounded processes and concepts. This definition can refer to both habitat loss and fragmentation per se (i.e., a change in habitat configuration), can be measured at the patch scale or the landscape scale, is used to refer to either the loss of habitat or the loss of a cover type, does not require that the multiple cover types that some species require are accounted for, may not account for the scale at which a species interacts with the landscape, and does not usually distinguish between human-caused fragmentation or natural fragmentation. Each of these areas of confusion is described in further detail.

Habitat Loss versus Habitat Fragmentation

Habitat fragmentation involves both habitat loss and a change in the configuration of habitat (Andr  n, 1994; Fahrig, 2003). Use of “habitat fragmentation” to describe both processes obscures the fact that the habitat loss has a much stronger negative impact on biodiversity than fragmentation per se, which generally has weak effects that can be both positive and negative for the biodiversity (Fahrig, 2003, *see Effects of Habitat Loss and Fragmentation: Habitat Loss is More Devastating than Fragmentation per se*). The correct emphasis on habitat loss can be particularly important when management decisions (e.g., whether to increase habitat amount or reduce subdivision) are being made (Lindenmayer and Fischer, 2007).

Landscape Scale versus Patch Scale

Island biogeographic theory (MacArthur and Wilson, 1967) greatly increased interest not only in the consequences of habitat fragmentation but also led to an overemphasis on patch-level (“island”) measurements rather than landscape-level measurements (Laurance, 2008). Many habitat fragmentation studies (possibly more than 50%, Fahrig, 2003; McGarigal and Cushman, 2002) measure fragmentation using patches as the unit of replication (e.g., they measure isolation and size of individual patches rather than habitat loss over the entire landscape), which can create confusion when making inferences at the landscape scale. If all patches are in the same landscape, then inference regarding the landscape scale effects of fragmentation is impaired by the lack of replication at the landscape scale (Delin and Andr  n, 1999). Inferences at the patch scale cannot necessarily be scaled up to inferences at the landscape scale without explicit consideration of landscape scale measurements because qualitatively different patch characteristics can result from the same amount of habitat loss (Figure 3; Fahrig, 2003).

Habitat Loss versus Loss of a Cover Type

The term “habitat” is defined as the place where an organism normally lives (Ricklefs, 2008), but is often used to refer to a natural cover type (e.g., forest) whether or not the taxon of interest normally lives there. For example, some species thrive

Figure 2 Landscapes near Ottawa, Ontario, Canada, which differ in the amount and fragmentation of forested habitat. Green areas indicate forest. Other habitats (agriculture, roads, and water) are shaded in white. Although most habitat loss involves both reduced amount and increased fragmentation (breaking up into pieces), these landscapes were selected to have independent variation in habitat amount and fragmentation: (a) high amount, low fragmentation; (b) high amount, high fragmentation; (c) low amount, low fragmentation; (d) low amount, high fragmentation. Adapted from Ethier K and Fahrig L (2011) Positive effects of forest fragmentation, independent of forest amount, on bat abundance in eastern Ontario, Canada. *Landscape Ecology* 26: 865–876.

in human-dominated cover such that it constitutes habitat from the species' perspective. When measuring natural cover (e.g. forest amount) to estimate habitat amount one might erroneously conclude that species abundance is improved by "habitat" loss, when that species' habitat is actually the cover type (e.g., agriculture) that increased with human landscape modification.

The use of natural cover types as an approximation for habitat is common because most species decline with decreased natural cover, but the exceptions to this rule can make the use of "habitat" to mean "natural cover" misleading. Species richness declines with loss of natural cover for most groups (bacteria, Gans *et al.*, 2005; birds, butterflies, canopy beetles, canopy ants, and termites, Lawton *et al.*, 1998; forest birds, molluscs, and lichens, Moning and Müller, 2009; and spiders, Prieto-Benítez and Méndez, 2011). However, a significant number of species benefit from human-dominated cover. Edge- and matrix-favoring groups in the Amazon benefit from forest loss (Laurance *et al.*, 2002), and some prey species can increase in abundance following habitat loss, if the habitat loss has a larger negative effect on the predators than on the prey (Ryall and Fahrig, 2005; Ryall and Fahrig, 2006). Measurement of a cover type without reference to a species use of it can lead to confusing conclusions about the effect of habitat loss (Lindenmayer and Fischer, 2007).

Even if a cover type reflects an accurate measure of habitat, it may be insufficiently precise. Holland *et al.* (2005) found that the amount of forest in the surrounding habitat was more strongly related to the abundance of beetles that relied on multiple food sources than the abundance of beetles that relied on a single food source. They hypothesized that this occurred because the specialist feeders were each limited to specific stand types within a forest and the generalist feeders were more tightly associated with forest cover in general.

Landscape Complementation

For some species, measurement of a single cover type may be inadequate because their habitat includes multiple cover types. Leopard frogs, for example, require spring breeding habitat (ponds), summer foraging habitat (grassy meadows), and overwintering habitat (streams or lakes). In a study of landscape effects on local leopard frog abundance, researchers were unable to detect an effect of breeding habitat amount on abundance in focal ponds unless the amount of summer foraging habitat was also included in their model (Pope *et al.*, 2000).

Scale of Effect

The spatial extent at which cover is measured influences the ability to accurately identify the relationship between landscape structure and population or community outcomes. Numerous studies show that the spatial extent over which habitat is measured influences the strength of the relationship between habitat and the response of interest (e.g., abundance), and that this "scale of effect" is species specific (Carr and Fahrig, 2001; Holland *et al.*, 2004; Roland and Taylor, 1997; Steffan-Dewenter *et al.*, 2002). Failure to measure habitat at the scale of effect can lead to the erroneous conclusion that habitat amount is not associated with biodiversity (Holland *et al.*, 2004). When researchers are unsure of the scale at which a species responds to the landscape, a common solution is to measure landscape features at multiple spatial scales to find the one that best correlates with the response of interest (Holland *et al.*, 2004). A simulation study indicates that the maximum dispersal distance recorded for a species is likely to be a good estimate of the scale of effect (measured as the diameter of a circular landscape surrounding a focal area, Jackson and Fahrig, in preparation).

Grain, or the resolution at which landscape structure is defined, may also influence the ability to detect relationships between species and landscape structure. Animals are expected to have a "functional grain" or the smallest spatial scale at which they recognize spatial heterogeneity (Baguette and Van Dyck, 2007). If the grain of a landscape is defined too coarsely (e.g., the finest resolution is larger than a species' average dispersal distance), important relationships between a species and landscape structure may be overlooked.

Human-Caused Fragmentation versus Natural Fragmentation

Habitat fragmentation is sometimes used to refer to both natural fragmentation (e.g., forest patches separated by fire-maintained savannah) and human-caused fragmentation (e.g., forest patches separated by agricultural land). Species in

Figure 3 Illustration of how potential effects of habitat loss on measures of habitat fragmentation can be contrary to commonly expected effects. The commonly expected effects of habitat loss are an increase in the number of patches, an increase in mean isolation (here measured as nearest neighbor distance), a decrease in mean patch size, and an increase in total edge. Effects which are contrary to these expectations are italicized. Empty rectangles indicate areas of habitat loss. Adapted from Fahrig L (2003) Effects of habitat fragmentation on biodiversity. *Annual Review of Ecology, Evolution, and Systematics* 34: 487–515.

naturally fragmented habitats have presumably adapted to natural fragmentation such that their movement behavior (Fahrig, 2007) and population response (Bunnell, 1999; Haila, 2002) to fragmentation will be qualitatively different from species confronted with fragmentation in formerly contiguous habitats.

Precise Language Facilitates Informative Science and Clear Management Directives

A vague conceptualization of habitat fragmentation can lead to several problems. Inadequate separation of the processes involved in habitat fragmentation can lead to the false impression that the effects of fragmentation cannot be generalized (Fahrig, 2003). The effects of fragmentation can be generalized when the aspect of fragmentation that is measured is explicitly defined and the other aspects of fragmentation are held constant. In addition, the illusion of a single process of habitat fragmentation has led to the misconception that one measure of the habitat fragmentation is equivalent to another

(Fahrig, 2003). Without carefully delineating terms, one might be led to believe that any measure of fragmentation refers in the same way to the broader concept when in fact different metrics measure different processes. Finally, linguistic uncertainty can make management decisions more difficult (Regan *et al.*, 2002).

The main remedy for confusion surrounding the broad conceptualization of fragmentation is precise communication concerning what aspect of human landscape modification is being measured. Fahrig (2003) recommends that “fragmentation” be reserved for the breaking apart of habitat after accounting for habitat loss – fragmentation per se. Fischer and Lindenmayer (2007) also warn against “double-booking” for the term “habitat fragmentation” which can refer to both the broad concept (that includes everything discussed in this section) and the narrow definition of change in configuration after accounting for loss. They recommend that the broad concept be termed “human landscape modification” and accept Fahrig’s suggestion that the narrow concept be called fragmentation per se. Ewers and Didham (2007) defend the use of “habitat fragmentation” for the broad

concept as an aid to communicating ideas across related studies but support other authors in their insistence that the specific way in which habitat fragmentation is measured should be clearly defined.

Careful language will improve the communication of ideas, but definitive separation of the various mechanisms conceptualized in the term habitat fragmentation also requires improved study design. Fahrig (2003) recommends that habitat loss and fragmentation per se be controlled, experimentally if possible, but statistically if necessary.

Effects of Habitat Loss and Fragmentation

Habitat Loss is More Devastating than Fragmentation per se

Measures of habitat configuration are almost always strongly correlated with habitat amount (Figure 4; Fahrig, 2003; Hargis *et al.*, 1998) making it difficult to discern whether the effects of human landscape modification are due to habitat loss or fragmentation per se. When the effect of fragmentation per se is measured independently from habitat amount (either by statistically or experimentally controlling for habitat amount), the effect size of habitat loss on biodiversity is usually much larger than that of habitat fragmentation per se. When fragmentation per se does have an effect, it is just as likely to be positive as negative (reviewed in Fahrig, 2003).

Habitat Loss is Associated with Greater Extinction Probability and Reduced Species Richness

Large amounts of habitat are expected to result in positive effects for populations and communities for a number of reasons. At the population level, greater amounts of habitat sustain larger population sizes, which are less susceptible to stochastic extinction (MacArthur and Wilson, 1967) and genetic drift (Wright, 1931). At the community level, lower extinction rates in areas with more habitat are expected to lead to greater species richness (MacArthur and Wilson, 1967). In addition, large areas of natural cover are more likely to include a larger variety of habitat types with their associated species (Williams, 1964). Greater species richness may also occur in larger areas simply because larger areas allow for a larger sample of species from a regional species pool, resulting in a greater number of rare species (Connor and McCoy, 1979).

Fragmentation per se Can Have Both Positive and Negative Results

Fragmentation per se is expected to lead to negative effects if it results in smaller, less viable populations or if the increased exposure to edge is detrimental (Bender *et al.*, 1998). Although the negative effects of habitat loss are expected to result from a reduced number of individuals, cover types, and species, fragmentation per se is generally assumed to reduce the probability of successful movement. This is likely a false

Figure 4 Illustration of typical relationships between habitat amount and four measures of fragmentation. Each data point corresponds to an individual landscape. Adapted from Fahrig L (2003) Effects of habitat fragmentation on biodiversity. *Annual Review of Ecology, Evolution, and Systematics* 34: 487–515.

dichotomy, however, because habitat loss itself reduces dispersal success by increasing the distances among patches (Fahrig, 2007).

Fragmentation per se implies a greater number of smaller patches. If the cost of crossing matrix is too high to allow for regular movement among patches, then individual subpopulations operate more or less independently. As in classic metapopulations (Hanski, 1994), the resulting small, isolated subpopulations are more susceptible to extinction.

A greater number of smaller patches also results in a higher perimeter to area ratio over the landscape. More frequent encounters with edges often increases emigration rates (Kareiva, 1985), thereby increasing the probability of dispersal mortality (Fahrig, 2001). Some matrix types are particularly risky and can have strong effects on population density (e.g., roads, Fahrig *et al.*, 1995).

Edges themselves can represent areas of decreased habitat quality. The Biological Dynamics of Forest Fragments Project documented strong effects of edges in a tropical forest, including the following: enhanced wind disturbance, increased tree mortality, invasion of disturbance-adapted species, altered species composition, lower relative humidity, decreased soil moisture, lower canopy height, decreased canopy foliage, increased temperature, and increased litter (reviewed in Laurance *et al.*, 2002). Negative edge effects are not as well-documented in temperate areas and may be less common (Fahrig, 2003).

Receiving less attention in the habitat fragmentation literature is the fact that fragmentation per se is just as likely to result in positive population responses as negative ones. Fragmentation per se may lead to positive population responses if subdivision of habitat results in (1) greater coexistence of competitors (Chesson, 1985), (2) greater coexistence of predators and their prey (Huffaker, 1958), (3) lower probability of simultaneous extinction of an entire population (Heino *et al.*, 1997), (4) greater immigration into habitat due to larger perimeter to area ratio (Bowman *et al.*, 2002), (5) greater dispersal success due to shorter interpatch distances (Grez *et al.*, 2004), (6) greater landscape complementation (e.g., providing access between foraging and nesting sites for bats, Ethier and Fahrig, 2011), or (7) positive edge effects (e.g., increasing abundance of edge-favored species, Laurance *et al.*, 2002).

Increased Reproductive Rate Decreases Sensitivity to Habitat Loss and Fragmentation

Reproductive rate may be the most important factor influencing the amount of habitat required to sustain a population. Theory predicts the existence of a threshold amount of habitat at which a small loss of habitat propels the probability of population extinction from 0 to 1 (Fahrig, 2001; Lande, 1987; With and King, 1999). The minimum habitat requirement likely depends on the attributes of the species and the landscape. A simulation testing the relative importance of reproductive rate, emigration rate, matrix quality, and fragmentation (randomly distributed vs. clumps of habitat) showed that the most drastic differences in extinction threshold occurred when the reproductive rate was varied (Fahrig, 2001).

Empirical evidence supports the importance of reproductive rate. Among 41 breeding bird species, higher

reproductive rate is associated with lower minimum habitat requirements (Vance *et al.*, 2003). Likewise, for 17 mammal species, the sensitivity of abundance to road density declined with reproductive rate independently of body size (Rytwinski and Fahrig, 2011).

Mobility, Habitat Specialization, and Matrix Quality Interact to Alter the Effects of Habitat Loss and Fragmentation

Habitat loss may have particularly severe effects for species that do not avoid matrix. The negative effect is expected to be even stronger if the matrix is dangerous. This is likely because matrix avoidance and/or low mobility (low probability of moving and/or short dispersal distances) is expected to be common among species originating from naturally fragmented habitats surrounded by high-risk matrix (Fahrig, 2007). Species from naturally continuous habitat or with little exposure to high-risk matrix may not have evolved matrix avoidance and may therefore suffer greater mortality than matrix-avoiding species when encountering high-risk matrix resulting from habitat loss (Fahrig, 2007).

Theoretical and empirical studies support the important interaction between dispersal traits and matrix quality. Two studies of variation in matrix avoidance among butterfly subpopulations support the hypothesis that matrix avoidance is selected for when interpatch distances are high and probability of successful dispersal through matrix is low (Hanski *et al.*, 2004; Schtickzelle and Baguette, 2003). A simulation model testing the relative impact of the number of patches, the distance between patches, and matrix avoidance on population density found that matrix avoidance was the most important factor preventing population decline (Tischendorf *et al.*, 2005). A model by Fahrig (2001) showed that populations with increased movement probability (matrix avoidance was not modeled) required more habitat to persist. This result depended on the mortality risk in the matrix – when the risk of mortality in the matrix was low, the effect of movement on minimal habitat requirements was greatly decreased.

Low-contrast matrix (matrix similar in structure to habitat) is generally thought to be better tolerated by native species than high-contrast matrix, but this conclusion may depend on how “matrix” is defined – for habitat generalists, “matrix” may actually provide habitat. Matrix type was more important than fragment size when predicting the recolonization of many Amazonian insectivorous birds after deforestation, probably because the “matrix” in which forest regrowth was more rapid and was most likely to provide birds with foraging and breeding opportunities (Stouffer and Bierregaard, 1995). In other words, the secondary growth served as habitat (technically not matrix). Likewise, dung beetle assemblages largely returned to their pretreatment state 15 years after deforestation when fragments were surrounded by secondary growth forest. Again, this recovery was due to the ability of dung beetles to use resources in secondary growth forest (Quintero and Roslin, 2005).

Low-contrast matrix may be detrimental to populations if it fails to evoke matrix avoidance and provides no resources on its own. A planthopper specialized on cordgrass avoids crossing into natural mudflat matrix but crosses easily into inedible, nonnative brome, which is similar in height to

cordgrass (Haynes and Cronin, 2006). Higher emigration into nonnative brome is associated with decreased density of planthoppers within cordgrass patches (Haynes *et al.*, 2007) and increased probability of planthopper extinction in cordgrass patches (Cronin, 2007).

Matrix heterogeneity can obscure the relationship between habitat loss and dispersal success. In both a simulation study and a field study of two mammal species, large patch size and short isolation distances were strong positive predictors of dispersal success when matrix was homogeneous, but the predictive value of these metrics was greatly reduced when matrix consisted of multiple cover types (Bender and Fahrig, 2005).

The interaction between matrix quality and mobility emphasizes that the important dispersal characteristic for populations is not so much low or high mobility, but high probability of success when dispersal is attempted (Callens *et al.*, 2011; Fahrig, 2007; Van Houtan *et al.*, 2007). For example, a simulation study suggests that high dispersal mortality can deplete genetic diversity more rapidly than complete dispersal avoidance (Jackson and Fahrig, in review). Simulation studies indicate that successful dispersal in patchily distributed habitats is likely to rely on matrix avoidance (Tischendorf *et al.*, 2005), linear movements in matrix (Zollner and Lima, 1999), strong ability to perceive habitat from a distance (Zollner and Lima, 2005), and adequate energy storage (Zollner and Lima, 2005). Species with high rates of successful dispersal may have been less vulnerable during past mass extinction events (Stork *et al.*, 2009), potentially because of their ability to spread the risks of environmental and demographic stochasticity over a large area and to avoid inbreeding depression (reviewed in Bowler and Benton, 2005).

In summary, population health after human landscape modification depends strongly on the interactions among matrix quality, habitat specialization, and the response of species to matrix during dispersal.

The Effects of Habitat Loss are Often Exacerbated by Additional Environmental Threats

Habitat loss usually cooccurs with other environmental threats (Laurance and Useche, 2009). In a study of vertebrate species listed under International Union for Conservation of Nature (IUCN), the most common pair of threats was agriculture (the most common reason for habitat loss) and hunting (Laurance and Useche, 2009). Human landscape modification results in more edge, providing easier access for hunters than is available in continuous forest. In the Amazon, for example, small forest fragments tend to experience much greater hunting pressure than large forest fragments (Peres, 2001), which can result in local extirpation of game species (Cullen *et al.*, 2000).

Habitat loss can lead to increased fire frequency in the tropics. Forested edges tend to be significantly drier than forest interiors (Kapos, 1989) and often about slash and burn agriculture in the tropics (Cochrane and Laurance, 2002). In one such region, forest fires on forest/agriculture edges occurred every 5 years, whereas the fire interval averaged 120 years in core forest areas (Cochrane and Laurance, 2002).

Habitat loss is also expected to exacerbate the effects of climate change on species. Poleward range expansion is hypothesized to be impaired if human landscape modification limits poleward movement or decreases population growth rate (Opdam and Wascher, 2004). One area of active research is the identification of areas of habitat conservation priority based not only on current habitat use but also on projected future distributions of species under various climate change scenarios (Olson and Lindsay, 2009).

Summary

The global scale of human landscape modification is staggering. Amelioration of its effects depends in part on clear communication. To enable understanding of the effects of habitat loss and fragmentation, practitioners must (1) clearly define which aspect of human landscape modification (habitat loss or some metric of fragmentation per se) they are discussing, (2) make measurements at the scale (patch or landscape) that will yield the most interpretable results (usually landscape scale with replication), (3) clearly define what constitutes habitat to the taxon of interest, (4) measure habitat at the spatial extent appropriate for the taxon of interest, and (5) delineate between natural and human-caused fragmentation. Habitat loss is a bigger problem than habitat fragmentation per se and should be the main focus of study and management. Fragmentation per se is expected to be a problem when it leads to smaller, isolated populations or when negative edge effects are expected to be prominent (e.g., in tropical systems). The effect of habitat loss is modified by species and landscape characteristics. An increase in reproductive rate decreases the amount of habitat required to sustain a population. High mobility is associated with high sensitivity to habitat loss if dispersal mortality is high, but some successful dispersal may be required for long-term persistence. Habitat loss and fragmentation are seldom the only threats in an area – they are often coupled with hunting, fire, and other threats, which should be taken into account.

Human Impact on Biodiversity, Overview

Leslie E Sponsel, University of Hawai'i, Honolulu, HI, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Anthropocene The name proposed for the geological epoch beginning with the Industrial Revolution characterized by the increasingly dominant influence of humans on the planet's atmosphere, hydrosphere, biosphere, pedosphere, and lithosphere.

Cultural ecology Analysis of how culture influences the interactions between a human population and the ecosystems in which they reside; also called ecological anthropology.

Culture System of socially learned, shared, and patterned ideas, institutions, behaviors, and their material products that distinguishes a particular society.

Diversity principle General geographical coincidence between high concentrations of both biological and cultural diversity, usually in the tropics.

Ecological transition Tendency for societies to be in growing disequilibrium with their biophysical environment as they increasingly deplete natural resources and degrade their habitat, thereby reaching new thresholds of environmental impact.

Historical ecology Transdisciplinary and diachronic analysis of how human societies and ecosystems change

and in turn transform one another through time in local and regional landscapes. Data are drawn from geology, archeology, history, and other sources.

IPAT A mathematical formula for calculating human impact on the environment expressed as
$$\text{Impact} = \text{Population} \times \text{Affluence} \times \text{Technology}.$$

Overexploitation Harvesting a population or resource at a rate greater than its natural replacement rate, which is the opposite of sustainable use.

Swiddening Umbrella term including diverse types of horticulture in which a small section of forest is cut and burned to plant crops in a temporary garden; shifting cultivation is used as a synonym, but slash-and-burn cultivation is now considered to be a pejorative term.

Traditional or local environmental knowledge (TEK) Detailed and accurate knowledge about the environment, including biotic species and ecological processes, that many indigenous and other peoples have developed and accumulated, and apply in their daily and intimate interactions with their habitats and in their system of natural resource use and management. The study of TEK is included within ethnoecology.

Introduction

Throughout human prehistory and history, human impacts on biodiversity have reached progressively higher thresholds. The net impact of humanity has been to reduce biodiversity. However, at the population level, the types and magnitudes of human impacts on biodiversity vary tremendously through space and over time, depending on the specifics of the particular context. Most societies have decreased local biodiversity, but many others have sustained or even increased it. Because the direct and indirect impacts of humans on the environment are nearly ubiquitous almost any biodiversity research and conservation must take the possibilities of human influence into consideration. As Western (2001) observes, "Conservation philosophy, science, and practice must be framed against the reality of human-dominated ecosystems, rather than the separation of humanity and nature underlying the modern conservation movement." Accordingly, this article explores successive thresholds of human impact on biodiversity in terms of biodiversity modification, conversion, commodification, and toxification. It concludes with a discussion of biodiversity futures. (Major surveys of this subject include Marsh, 1864; Thomas, 1956; Turner *et al.*, 1993; McNeely *et al.*, 1995; Goudie and Cuff, 2002; Myers and Kent, 2005; Sodhi and Ehrlich, 2010).

Principles

Human and Environmental Diversity

Not all humans are equal in their impacts on biodiversity. Although it is widely recognized that there is tremendous diversity in nature, there is also considerable diversity in humanity. Nearly 7000 distinctive cultures exist today and there were many times more in the past, probably on the order of at least tens of thousands over some four million years of human existence. Accordingly, there is tremendous diversity in human relationships with and impacts on biodiversity. In examining human impacts, it is imperative to consider the diversity of humans through time (prehistory through history) and space (cultures and regions).

Environmental diversity is another variable in determining the human impact on biodiversity. Some environments are simply much more fragile and vulnerable than others, especially those that are relatively simpler, such as the arctic and deserts, and those that are isolated with a high proportion of endemic species, such as oceanic islands. Also, some regions are simply much less accessible or hospitable to humans than others, including the poles, mountain heights, deserts, and deep oceans. In these cases, the label "wilderness" may still apply – pristine nature that is largely unaffected by humans.

Furthermore, given the dynamism of ecosystems and ecological processes, together with the widespread impact of humans on them, it is misleading to consider most environments as pristine, virgin, primeval, or wilderness. The condition of any ecosystem is the cumulative product of previous conditions, usually including human impacts. The more important question is not whether or not a human society had or has any environmental impact, but its particular forms and magnitude, and if negative then the extent to which it is reversible and allows natural regeneration within a normal period of time.

In studying human impact it cannot be assumed that the previous environment was in a state of equilibrium or climax stage in ecological succession. Furthermore, even when humans are a factor in environmental change, it cannot be assumed that other agencies, such as natural alterations in climate or weather and natural fires, are not also contributing to change.

In any case, it is unrealistic to consider biodiversity anywhere without also considering the possibilities of human influence. Human impact is inevitable because, ultimately, biodiversity is the primary or raw natural resource that all societies rely on for their subsistence and economy. Also, biodiversity is the biotic component of ecosystems and ecological processes on which human survival, adaptation, and welfare ultimately depend. Another term for human impact that has become popular is ecological footprint.

Types of Impact

Human impact on biodiversity, direct or indirect, involves four basic factors: (1) overexploitation of natural resources; (2) habitat modification, conversion, and fragmentation; (3) the introduction of exotic (nonnative) species; and (4) pollution. Any one of these four factors may influence ecosystem composition, structure, and function; ecological processes; and biodiversity, especially through species extinction. Documented extinctions during the past 400 years include 484 animal species and 654 plant species, but this must be only a fraction of

the actual total (Heywood, 1995:198). However, in some circumstances, the second and third factors may increase biodiversity locally, because some components of biodiversity are anthropogenic (human-caused). In Britain, for example, there has been a net increase in mammalian diversity as 21 of its 49 species are introductions (Heywood, 1995:757).

Human populations may influence biodiversity at the genetic, population, species, ecosystem, biome, and/or biosphere levels of the ecological spectrum. Because species as well as ecosystems are interrelated and interdependent, human impact on any one species or ecosystem may influence others as well, much like a chain reaction often referred to as a cascade effect.

Species and Population Levels

Globally humankind has increasingly tended toward greater levels of ecological disequilibrium, that is, with many (but not all) populations exceeding the carrying capacity of their habitat, depleting resources, degrading environments, and thereby threatening and reducing biodiversity. There have been at least seven successive thresholds of environmental impact in cultural evolution, their inception approximated in years before present and varying regionally: the use of fire by foragers (hunter-gatherers) (0.5 million), farming (5000–10,000), cities (5000–6000), exponential growth in the human population (1000), European colonialism (500), industrialization (150–200), and globalization (50). These thresholds are part of a continuum or gradual process, although an accelerating one. (These thresholds are somewhat analogous to the states of water as ice, liquid, and gas. The substance – H₂O – is the same, but a gradual quantitative increase in temperature leads to major qualitative changes in its physical properties.) In the case of sociocultural evolution, scale of complexity is a pivotal factor (see [Table 1](#)).

At the population level, the situation is complicated. Long ago some societies developed relatively sustainable economies that did not markedly endanger or reduce biodiversity, as

Table 1 General trends in sociocultural evolution correlated with increasing thresholds of human impact on biodiversity

1.	Population – nomadic to sedentary settlement pattern with increasing population density, nucleation (settlements to cities), and pollution.
2.	Food – wild to domesticated foods with shift from foraging to farming, and polycropping to monocropping
3.	Energy – somatic (human and animal) to extrasomatic (water, wind, wood, fossil fuel, nuclear) sources of energy for work
4.	Land – extensive (horticultural) to intensive (agricultural) land use; land tenure – community/public to private/corporate ownership
5.	Economy – subsistence (satisfying basic physiological needs) to market of surplus production to materialist consumerism; local selfsufficient to regionally and then globally interdependent economy (globalization)
6.	Waste – organic products that are readily biodegradable to more recently those like metals and plastics that disintegrate very slowly and are toxic
7.	Scale – small and decentralized to large and centralized societies (states), the latter with increasing import of natural resources from ecosystems in distant regions
8.	Differentiation – egalitarian to hierarchical (stratified) societies, the latter with increasing inequality in access to resources, goods, and services and institutionalized warfare with militarization of institutions and regions
9.	Alienation – daily to occasional contact with and feedback (monitoring human impact) from the natural environment; eventually with alienation from nature and other humans, and increasingly decisions made by agents far removed from the locations they affect
10.	Worldview – ecocentric to anthropocentric and egocentric worldviews, attitudes, and values; also sacred/moral to secular/amoral and utilitarian orientation to nature; may include shift from biophilia (love of nature) to biophobia (fear of nature)
11.	Balance – some degree of dynamic ecological equilibrium with recognition of limits to increasing disequilibrium with the false assumption that there are no limits (i.e., ecological transition)
12.	Impact – environmental modification to conversion (natural to cultural landscapes) and fragmentation (remnant patches of nature); also toxification with industrialization; local to global impact on biodiversity and ecosystems

evidenced by their longevity in prehistoric and historic records. Some societies even increased biodiversity. Furthermore, the same society may increase biodiversity in certain ways, yet decrease it in others. Thus, human impact varies in time and space as well as with different species, ecosystems, and biomes. Consequently, any generalizations about human impact must be carefully scrutinized with attention to temporal and geographic scales as well as the specific details of the particular cultural and ecological contexts.

It follows that a holistic anthropological approach, one emphasizing cultural and historical ecology, is indispensable for assessing the possibilities of human impact on biodiversity in any context. It could even be argued that cultural and historical ecology are indispensable for understanding biodiversity itself, because it is so rarely free from some degree of human influence, at least indirect. Indeed, biodiversity as a concept is a Western cultural construct developed at a particular stage in history, even if the associated biophysical phenomena are undeniably real.

Ambivalence

Biologists and others have been ambivalent about the human species. Most would readily consider *Homo sapiens* to be a part of nature as a product of biological evolution, but apart from nature in terms of ecology. However, in much of the past and in many cases to this day, human populations are simply one component in the dynamics of ecosystems and ecological processes. The idea that humans are unique and apart from nature may derive from the anthropocentrism (human centeredness) of Western civilization and of Christianity, Judaism, and Islam. (Anthropocentrism is also a contributing cause of the environmental crisis.) In fact, every species is unique as a closed genetic system and in other respects. However, it may be valid and useful to view *H. sapiens* as the dominant or most important keystone species in many if not most ecosystems. (A keystone species is one that has an unusually important influence on other species and the ecosystem.)

An important example of such anthropocentrism is the common view that human impact on the environment is necessarily an unnatural disturbance. All organisms affect their environment in various degrees and ways; consider the various impacts of trees, fungi, earthworms, leaf-cutter ants, bees, woodpeckers, kangaroo rats, prairie dogs, beavers, wild pigs, primates, bats, elephants, plankton, starfish, and sharks. However, nonhuman organisms that influence their environment are rarely considered a disturbance, except for invasive species or exotic species introduced by humans. Usually only when an organism depletes resources and degrades the habitat beyond its natural capacities or normal period for regeneration might the term disturbance be appropriately applied. Yet it could be argued that some human societies are unnatural or even antinature, especially industrial ones. Other societies appear to be an integral part of nature, such as many more traditional indigenous cultures in the Amazon forests like the Yanomami. The impact of such societies on their environment is usually no less natural than that of other species. This was likely the case for the majority of societies through most of human existence.

Biodiversity Modification

Extinction Hypothesis

Human antiquity markedly varies among regions, and consequently so does cumulative impact. Hominins (the human line) evolved in Africa some four to six million years before the present. Human dispersal into other regions is approximately dated as follows: Europe and Asia (1 million), Australia and New Guinea (50,000–60,000), the Americas (12,000–20,000), and Pacific and other islands (30,000–to recent, depending on the island) (Bodley, 2011).

As humans colonized new regions, supposedly they would have a great advantage over the prey that lacked previous experience with them. Relatively suddenly the hunters became a new top carnivore in the food web, rather than through the usual gradual process of predator–prey co-evolution. Furthermore, their technology provided advantages, particularly projectile weapons like the spear that allow some safe distance from and surprise for prey when making a kill. Indeed, Paul S. Martin and others hypothesize that the dispersal of humans into new areas caused massive faunal extinctions as early as around 50,000 years ago, depending on the region, especially in Australia, the Americas, New Zealand, Oceania, and Madagascar. The main basis for the so-called “blitzkrieg hypothesis” is the apparent coincidence in timing of human arrival and massive megafaunal extinctions. However, with little to support it but circumstantial evidence, this hypothesis remains far from conclusively proven, and it is much more problematic and controversial than advocates usually admit. For example, convincing evidence is lacking in Australia for a temporal coincidence between human dispersal and megafaunal extinctions. Yet even if temporal coincidence were demonstrated, that does not automatically prove a cause–effect relationship nor exclude other potential causal factors such as climatic change instead or in addition. In New Zealand, however, there is no doubt that overhunting and habitat destruction by indigenous people (Maori) caused the extinction of many animal species, including the large moa birds.

Whether examining faunal extinctions or any other aspect of human impact on biodiversity, human diversity must be taken into account. Even in especially vulnerable ecosystems, different cultures may have very different impacts, such as indigenous peoples and subsequent colonists in Hawaii. Hawaiians introduced 34 exotic species and supposedly caused the extinction of some 50 endemic species during their more than 1500 years of exclusive occupation. In contrast, European, Asian, and other colonizers introduced 4653 exotic species, caused the extinction of 211 endemic species, and endangered more than 800 others, all in a little over two centuries. Consequently, compared with native Hawaiians, subsequent colonizers caused 137 times as many introductions and four times as many extinctions, all in a mere one-seventh of the time (Sponsel, 2001).

In general, traditional hunter–gatherers and others may seem to have a very limited impact on their environment, given their low population density, high mobility, limited technology, subsistence economy, minimal needs and wants, intimate environmental knowledge and monitoring, and Animistic worldview, attitudes, and values that are nature oriented.

Nevertheless, even small bands of nomadic foragers can have some impact, for example, on seed dispersal; one way archaeologists identify prehistoric occupation sites such as hunting camps is by distinctive combinations and concentrations of useful plant species that would not likely occur naturally.

Fire

Natural fires have influenced ecological systems and processes for many millions of years. In contrast, so far evidence indicates that the human use of fire extends back at least half a million years in the Old World to the later portion of the period of *Homo erectus*, but it could be twice or more that length of time. Usually the main reason hunters burn an area is to create fresh plant growth to attract game. In addition, low-intensity fires set by indigenes prevent the accumulation of fuels that might otherwise lead to devastating wildfires, especially during a dry season, drought, or from lightning strikes. (This is a lesson only recently learned by national park managers in the US, Australia, and elsewhere). Controlled burning of different patches of the landscape at different times by indigenes or others may help increase biodiversity, whereas wildfires may decrease it.

The long-term cumulative effect of burning by foragers can be substantial, as in the case of the so-called fire-stick farming by the Aborigines of Australia more than some 50,000 years (Flannery, 1995). Repeated burning of large areas of vegetation over long periods would eventually significantly modify the plant community and consequently also the associated animal community. Sometimes a pyrosere is created, a biotic community resistant or adapted to fire that is prevented from further ecological succession or development by repeated burning. With the regular and widespread use of fire by foragers, surely a new threshold in impact was reached. Some grasslands in temperate and tropical zones, such as the Scottish highlands and Venezuelan llanos, respectively, may be the result of repeated burning by humans at least in part, although in many areas this conclusion is still controversial and climatic change may be a factor as well. Fire can also increase the biodiversity of an area, among other things, by creating a mosaic of plant communities at different stages of succession.

Horticulture

Fire is also an important component of farming technology. In tropical forests, during the dry season a plot of about a hectare or so of vegetation is cut and then, after drying out in the sun, it is burned. The organic ash from the burn provides fertilizer for the growth of crops that are planted just before the rainy season. This ash can be critical because tropical soils are usually poor. The crops are often pioneer or weed species that thrive in disturbed areas. Swiddening in some form is not only ubiquitous throughout tropical forests, but was also practiced by pioneer farmers in Europe and America.

Traditional swiddening may enhance biodiversity. This practice creates a gap in the forest that provides sunshine for crops. They are harvested for a few years and then less intensively as productivity declines with decreasing soil fertility and increasing problems with weed competition and pests. Over

years or even decades, the swidden gradually converts into fallow, with successional plants growing from seeds left in the soil and entering from surrounding forest through agencies like wind and birds. Consequently, swiddening leads to a mosaic of plant and associated animal communities at different stages of succession. Swiddening also forms ecotones (transition zones between two environments) that may increase biodiversity (edge effect) by harboring some species from both environments and others specializing on the ecotone. Such environmental heterogeneity increases the potential for higher biodiversity. Gardens and fallows also attract game and other animals, given the concentration of vegetation on the ground that provides cover and a concentration of edible plants, unlike a primary forest in the tropics.

Swiddening enhances biodiversity at the genetic level as well, since most swiddens are polycrops (numerous species and varieties) of domesticated plants. Crop diversity reduces the risk of total failure as a result of weather, disease, or pests, because some species and varieties are more resistant or resilient.

As a result of the variety of human uses and manipulations of forests, it cannot simply be assumed that any are entirely pristine. In the Amazon it is estimated that nearly 12% of the forests beyond the floodplains are to some degree anthropogenic (Balée, 1994). For some two decades, researchers at La Selva, the famous tropical biology research station in Costa Rica, thought that they were studying natural forest. They were unaware that it was to some extent anthropogenic until the discovery of charcoal and pottery fragments in the soils. In Africa, conservationists assumed that forest patches in savanna grasslands were relics of formerly more widespread forest. However, studies demonstrated that many of these forests are not natural relics of high biodiversity, but are established, used, and managed by local villagers (Fairhead and Leach, 1996). In many instances, farming may grade into forestry with agroforestry (mixed tree crops) as an intermediate phase.

Under traditional conditions – low density of the human population, a subsistence rather than market economy, adequate fallow periods, and extensive forest for future gardens – swiddening is usually sustainable, that is, it does not irreversibly deplete natural resources and degrade ecosystems. Indeed, it does not appear that forests like the Amazon were ever endangered, even after centuries or millennia of indigenous activities, until the encroachment of Western civilization and particularly in recent decades. However, in most areas traditional conditions no longer hold.

However, there are cases where swiddening has a negative impact. As an example, changes in plant species diversity over the past 14,000 years in Panama are preserved in phytoliths (plant fossils) from lake sediments. A sharp decrease in this diversity coincides with the onset of swiddening around 7000 years ago and may be causally related (Piperno, 1994). Thus, human impact on biodiversity from swiddening and other activities needs to be assessed on a case-by-case basis.

Still, traditional shifting cultivators contrast markedly with shifted cultivators of recent decades, the latter being immigrants who colonize tropical forests, often as economic refugees. Pioneer swiddeners are much more likely to contribute to deforestation because of their lack of familiarity with farming in a tropical forest and orientation to a market economy rather than mainly subsistence. This is the case with

people moved by the Indonesian government in its transmigration program from islands with high human population density like Java to those with low density like Irian Jaya. A similar situation occurred when the Brazilian government built the Trans-Amazon highway as a way to relocate rural poor mainly from the northeast into the Amazon Basin.

Biodiversity Conversion

Agriculture

The shift from human modification to the conversion of environments and biodiversity pivots on the decline of rotational systems of land and resource use, a process usually associated with increasing population and economic pressures. Traditional foragers, herders, and swiddeners usually tend to maintain sustainable economies by rotating one or more of these factors: types of resources used as well as places, times, techniques, and personnel in resource exploitation. If rotation decreases, then human impact increases markedly and eventually conversion occurs instead of modification, reflecting an emphasis on intensive rather than extensive use of land. By various estimates up to 50% or more of the land surface of the planet has been converted by humans and 23.8% of potential net primary productivity is captured by humans (Haberl *et al.*, 2007).

Agriculture usually involves some kind of plow pulled by a domesticated animal, in contrast to horticulture, which usually involves only hand tools like an ax and digging stick powered solely by human muscle. Agriculture is a more intensive and permanent form of land use focused on conversion of the environment, whereas horticulture is a more extensive but temporary or rotational form of land use focused on modification of the environment. Accordingly, agriculture usually simplifies ecosystems and reduces biodiversity, whereas horticulture may sustain or even increase environmental heterogeneity and biodiversity. Agriculture also creates more environmental fragmentation than horticulture, that is, the dividing up of landscapes into isolated or semiisolated patches of natural environments such as forest remnants in farm fields. Again, whether horticulture or agriculture, it is necessary to assess the impact on biodiversity on a case-by-case basis. Nevertheless, since World War II, agricultural expansion and intensification have been major factors generating accelerating deforestation, most of all in the megadiversity countries of Brazil, Congo, Indonesia, and Mexico. However, it is possible for farming to generate diversity in domesticated and wild species.

Rice Paddies

Throughout Asia, large portions of the landscape, especially in the lowlands near rivers and streams, were converted centuries or millennia ago to wet rice paddies. Paddies can also be found in highlands where terracing has been developed. Conversion continues to this day, driven by increasing population and economic pressures on land and resources; it is accelerating in many areas. Conversion includes numerous types of forests, grasslands, and wetlands, and accordingly sacrifices an enormous amount of biodiversity. For instance, various types of forest covered about 70% of Thailand until World War II,

whereas today only about 15% of the country is forested, largely because of agricultural expansion and logging (Sponsel, 1998).

Rice paddies are not simple monocrops, however. There may be hundreds or even thousands of varieties of rice in a region. It is estimated that some 50,000 local varieties of rice existed in India until recently. In addition, there may be several hundred species of wild plants and animals associated with paddies, many of them considered edible. Beyond the paddies there are home gardens, fruit orchards, pastures, various types of forest, and agroforestry (tree crops), all of which contribute considerable biodiversity to the regional landscape. For instance, in parts of Bali, home gardens may contain as many as a hundred or more species of wild and domesticated plants.

Raised Fields

Extensive areas of raised or ridged fields are found in many parts of the world, usually along river floodplains or in other wetlands. They elevate land above water for farming. Soil is dug and piled on top of either side of a ditch to form a long mound. The ditch becomes a canal for water drainage and irrigation. On floodplains the ridges are arranged in parallel fashion perpendicular or at an angle to the river. Organic debris and sediments from the canals are periodically dredged and placed on top of the mound as a rich organic fertilizer. Fish, waterfowl, and other aquatic organisms thrive in the canals and are harvested for protein in the diet. Raised fields may increase productivity and biodiversity beyond the level that would otherwise exist in the region.

Vavilov Centers

Vavilov centers are concentrations of genetic and morphological diversity remaining at the several foci of plant and animal domestication from the Neolithic some 5000–10,000 years ago, the exact period depending on the region. These centers, as concentrations of landraces and their wild ancestors, are in effect *in situ* gene banks. (Landraces are species and varieties of domesticated plants and animals that have been genetically improved by traditional farmers and herders, but remain uninfluenced by modern breeding technology.) Prehistoric and historic farmers and herders engineered significant biodiversity in their crops and livestock, in part to reduce risk. For instance, some eight species and 3000 varieties of potatoes were cultivated in the Andes. As another example, today a single species of sheep (*Ovis aries*) includes more than 800 different breeds, many quite ancient (Heywood, 1995:111, 775). Vavilov centers are increasingly endangered and degraded by growing population and economic pressures. Thus, attempts at *ex situ* conservation of their biodiversity and seeds of other plant species may be the main hope for long-term preservation, such as in the Kew Millennium Seed Bank partnership, which has so far saved seeds of 10% of the wild plant species of the world with 60,000–100,000 species under threat of extinction. The loss of diversity in the varieties of domesticated species and their ancestors severely limits the potential for adaptive responses to future environmental changes and perturbations, whether natural or anthropogenic.

Population

It has been estimated that through agriculture and other activities, humans preempt at least 40% of the Earth's total primary biological production annually (Vitousek *et al.*, 1986). This magnitude of resource use surely diminishes the possibilities for many other species and the planet's biodiversity as a whole. Given projections for continued human population growth in this century before any global stabilization, surely this cooption of energy and nutrient sources from other species will get much worse. Indeed, some four dozen of the poorest countries will triple their populations within the next five decades. It is also noteworthy that about 40% of the human population lives within 60 miles of the coast which is often relatively rich in biodiversity, but is being increasingly impacted by sea level rise with global climate change.

The human population explosion is a relatively recent phenomenon. After some four million years of human evolution, the world population had only reached 300 million by AD 1000. Then world population grew to 500 million by 1500, 1 billion by 1900, and now nearly 7 billion. It is projected to be up to 10 billion by 2050 (Myers and Kent, 2005). Correlated with this growth is increasing population density. For example, generally in the tropics, human population densities (individuals per km²) are: foragers, <1; swiddeners, dozens; and wet rice farmers, hundreds to thousands. There are megacities with a population of more than 10 million. Increasing levels of population mean increasing impacts on biodiversity and the environment more generally (Bodley, 2008; Sponsel, 1998). A mathematical expression of such matters is IPAT, which is an acronym for $I = P \times A \times T$, wherein *I* stands for impact, *P* for population, *A* for affluence, and *T* for technology (Ehrlich and Holdren, 1971; O'Neill, 2002).

Though increases in the size and density of the human population certainly increase impacts on biodiversity, not all humans create the same impact, and some are grossly disproportionate. For example, upper- and middle-income consumers use resources and produce pollution at levels many times higher than lower-income consumers and the poorest, whether comparing economic classes within a single society or the so-called developed and less-developed countries – the core and periphery in the world economic system, respectively. This is the problem with labeling the entire human species as the dominant animal, it is mostly industrialization, rapacious capitalism, and the wealthy that impact the most on the environment (Ehrlich and Ehrlich, 2009). Because of their greater environmental impact, the wealthy nations, as well as petroleum, pharmaceutical, and other corporations, have a special responsibility to reinvest some of their profits to help fund biodiversity research, education, and conservation.

Biodiversity Commodification

Cities

Market economies and cities are largely responsible for the commodification of nature – the commercial or monetary evaluation of biota and landscapes. Because most urbanites

and suburbanites do not produce their own food, they must trade or purchase it and other natural resources as imports from the farmers working in the vast rural hinterland. Thus, commodification has been developing with urbanization for at least 5000–6000 years. Today about half of humanity resides in an urban environment, although this concentration, the megalopolis, and suburban sprawl are recent phenomena. In 1800 only about 3% of humanity lived in cities. Now there are megacities with a population above 10 million. However, it is not always easy to detect a clear boundary between urban, suburban, rural, and natural areas. Still, one thing is clear: urbanization will continue to increase around the world and variously impact biodiversity (Myers and Kent, 2005).

Another result of the commodification of nature, and a major strategy in biodiversity conservation that is mainly advocated by persons from the urban elite, is the economic valuation of environmental products and services, such as medicinal plants and other products from tropical rain forests. Although this approach may be necessary to counteract the economic pressures for large-scale resource extraction from national governments, corporations, and market forces, this sales pitch diminishes biodiversity by ignoring its diverse nonmonetary intrinsic values.

The human body is host to biodiversity in the form of a multitude of internal and external parasites and other microscopic to small organisms that inhabit and visit it, such as bacteria, fungi, mites, lice, mosquitoes, ticks, and leeches. Likewise, human habitations and settlements, especially cities, may be viewed as hosts to a peculiar assemblage of biota, mainly commensals and parasites, such as squirrels, dogs, cats, rats, mice, pigeons, cockroaches, and flies. Though cities are mostly anthropogenic environments, they may also preserve fragments or islands of nature of different sizes in the form of various parks (including botanical gardens, zoos, and aquariums), home yards and gardens, indoor plants, and pets. As an example, there are about 1000 species of plants in the parks and gardens of the city of Singapore. Immigrant and ethnic neighborhoods introduce biodiversity into cities through the distinctive variety of plant species cultivated in their home gardens. In some regions where biodiversity is naturally low, human habitations and settlements may elevate biodiversity beyond prior natural levels.

The microscopic level of biodiversity cannot be ignored. Large urban populations also serve as a reservoir for viruses and a variety of other microbes that transmit and maintain diseases. The emergence and reemergence of new infectious diseases and drug-resistant strains are other aspects of how microbial diversity and history are often linked to cities. The high density of the human population in cities not only creates sanitation and health problems for humans, but also degrades the water quality and life in nearby aquatic ecosystems, including in coastal zones where more than a third of humanity dwells.

Colonialism

Colonialism, in its various forms, has affected biodiversity throughout the world, and continues to do so. During the past 500 years, Europeans introduced plants and animals from the

Old World into their overseas colonies, especially areas that were climatically similar to parts of Europe, like portions of Burma, California, Chile, Kenya, and South Africa. This Europeanization of local ecosystems reduced native biota and created neo-Europes. The biological exchange also flowed in the opposite direction, however, from the New World (Americas) to the Old (Europe and beyond), with the spread of crops originally domesticated by prehistoric native Americans, such as potatoes, corn, squash, tomatoes, tobacco, cotton, and manioc. Indeed, today much of the world's food supply comes from introduced species (Crosby, 1986).

Biodiversity at the microbial level is another aspect of the so-called "Columbian exchange," the biological and cultural consequences of the Old World and New World on one another. Indeed, throughout the Americas epidemics of introduced Old World diseases caused catastrophic depopulation of indigenous communities. Because these populations had been isolated from the Old World for thousands of years, they had no previous experience with the Old World diseases to develop immunological resistance (Crosby, 1986). The devastating crash of their populations relieved pressure on their land, resource base, and local biodiversity. In many areas, forests and other environments regenerated rapidly, indicating that indigenes had not irreversibly degraded them. Moreover, the apparent demographic void and supposed wilderness encouraged European colonization of what appeared to them to be an underpopulated and underused frontier. This process continues to this day in parts of the Amazon and elsewhere (Denevan, 1992).

The Columbian exchange was certainly an unprecedented event in the history of human impact on biodiversity; however, it did not operate on any prior pristine nature. Long before European contact, the peoples of the Americas modified and in some regions converted many ecosystems (Denevan, 1992). For instance, in some areas of the ancient Mayan civilization there was an extensive deforestation. As another example, anthropogenic prehistoric shell middens (mounds) in riverine and coastal zones may have higher diversity and density of useful plant species than adjacent natural sites.

Europeans are not the only colonials, just those most familiar. All empires are built in part on geographic expansion through some combination of long-distance trade, military conquest, and domination and oppression (economic, political, social, cultural, and religious) for the exploitation of the land, resources, and labor of other societies. Some examples are the Aztec in Mexico; the Inca in the Andes; Arabs in many parts of Africa, Europe, and Asia; and Chinese in much of East and Southeast Asia. All empires affect local biodiversity through biotic exchanges and environmental modification and conversion. For instance, in Asia the geographical distribution of some plant species is inexplicable without considering the role of sacred species such as the bodhi or pipal tree (*Ficus religiosa*) in Buddhism and temple yards.

Modern Transportation and International Commerce

Long-distance ocean travel and trade became possible with the development of seaworthy ships some 6000 years ago, and

eventually facilitated European colonialism and widespread biotic introductions. However, intentional and unintentional introductions of species between formerly independent or isolated regions of the world have greatly accelerated with the advent of modern transportation and international commerce. More than 600 species of animals and plants are directly threatened by illegal international trade that involves more than ten billion dollars annually (International Union for the Conservation of Nature (IUCN), 2011).

The introduction of exotic species can endanger native species and ecosystems. For example, the introduction of the South American otter (*Myocastor coypus*) into southern Louisiana in the 1940s had profound consequences on the landscape and ecology of the Mississippi delta and marshes making flooding with storms more devastating such as in the case of hurricane Katrina. The inadvertent introduction of the brown tree snake (*Boiga irregularis*) from Papua New Guinea to the island of Guam in Micronesia caused the extirpation (local extinction) of a dozen species of native birds and still threatens other fauna. The zebra mussel (*Dreissena polymorpha*) accidentally spread from Europe into the Mississippi River basin of North America when a tanker dumped ballast waters in the Great Lakes. Among other problems, this exotic mussel now threatens numerous native mussel species. Many other examples could be given, for more than 4500 exotic species have become established in the United States during this century alone. Many exotic species, whether spreading naturally or introduced by humans, become invasive species severely disrupting ecosystems. The effect of species introductions worldwide probably results in a net loss of global biodiversity, and by now alien species have become the greatest threat to biodiversity second only to habitat destruction. However, in some areas, such as New Zealand and Hawai'i, net biodiversity has actually increased as the result of numerous introductions of exotic species, even though they variously threaten, endanger, or extirpate many native and endemic species.

Through European colonialism, Enlightenment ideals of rationalism and individualism, industrialization, capitalism, economic development, modernization, and globalization, the world's environments, lands, and natural resources, including biodiversity, have progressively become objectified and commodified. This desanctification of nature has been facilitated by the spread of some religions, especially the Abrahamic ones, that have usually suppressed if not replaced previous religions like Animism, which is usually more environmentally friendly (Harvey, 2006). All of this has greatly facilitated the overexploitation, degradation, and destruction of biodiversity throughout the world and in its last frontiers such as tropical forests. In turn, this trend has been magnified by the insatiable greed that is inherent in the competition and growth mania of capitalist economies and the associated culture of materialism and consumerism, including the recent processes of globalization. Biotic homogenization is now transpiring throughout the world.

This situation is compounded by the fact that the rich are getting richer at the expense of the poor who are becoming poorer. Wealthy entrepreneurs, multinational corporations, and the so-called developed countries can afford to buy greater access and rights to biodiversity, just as they also exert a

disproportionate impact on it. The poor are able and willing to pay less attention and money for biodiversity conservation than the rich, not necessarily because they are ignorant or unconcerned, but because they have fewer economic assets and alternatives (e.g., Stonich, 1993). During the 1997 economic crisis in Southeast Asia, for example, the harvesting and export of wildlife species and their products accelerated markedly as local people turned to their forests to generate desperately needed cash, as their regular farm crops and jobs no longer provided adequate household income. Material wealth and technology are concentrated in the developed countries in the Northern Hemisphere, whereas population growth, poverty, and biological wealth are concentrated in the so-called less-developed and developing countries of the Southern Hemisphere. Such inequities are a serious obstacle to biodiversity conservation as well as human rights and well-being.

Commercial Farming Industry

The beginnings of various agribusiness industries can be traced back to European colonialism. Most of these industries cause the massive conversion of forests and other ecosystems to monocrop plantations, such as in the tropics with bananas, cocoa, coconut, coffee, cotton, eucalyptus, oil palms, pineapple, rubber trees, sugarcane, tea, and tobacco. As a result, higher thresholds of environmental impact have been reached with extensive biodiversity loss at the genetic, species, and ecosystem levels, especially in fragile tropical islands.

Since the 1960s, the so-called Green Revolution and other forces of globalization have been threatening and diminishing the genetic and species diversity of domesticated plants and animals that have been developing since the Neolithic period. Monocrops from the Green Revolution are genetically engineered for rapid growth and high productivity in response to massive subsidies of chemicals as fertilizers, herbicides, and pesticides. However, because of the high costs of inputs, mechanization, and transportation, these agribusiness industries are grossly inefficient even if highly productive. Such monocrops are also much more vulnerable than the diverse agroecosystems of traditional farms to climatic changes and weather perturbations such as El Niño. Nevertheless, modern agribusiness, biotechnology and genetic engineering, and bio-prospecting are currently revolutionizing food production among other things, but with largely unknown yet probably far-reaching consequences from the erosion of agrobiodiversity and biodiversity and from chemical and genetic pollution.

The forests and woodlands of the world have declined significantly in area since the origin and spread of agriculture some 10,000 years ago. However, deforestation rates have surged dramatically in recent centuries, and especially in recent decades in the tropics. Although tropical forests cover only about 6% of the Earth's surface, they contain about half of all its biodiversity; thus they are the recent and future hot spots for biodiversity research and conservation. These forests are also increasingly becoming the hot spots of sociopolitical conflict and violence, such as in the Democratic Republic of Congo, Rwanda, Burundi, and Sierra Leone. Many temperate

forests are deteriorating from loss of old growth, acid rain damage, and other forces. However, the forest cover in New England has expanded as the farm economy declined over the past 100 years, a hopeful indication of nature's capacity for regeneration.

The combination of causes and the magnitude of deforestation and consequent biodiversity erosion have varied tremendously through time and space depending on the specific details of the particular context. The impact of a stone ax on tropical forest compared with a metal one is quite different, even allowing for cumulative impact with substantial human antiquity in an area. The introduction of more efficient metal tools and a market economy to trade local natural resources for Western manufactured goods have accelerated deforestation throughout the tropics. Moreover, in recent decades newer technologies, including chain saws and bulldozers, together with new economic enterprises and incentives, created unprecedented rates of deforestation. In many areas of the Brazilian Amazon, for instance, cattle ranching made possible by government tax support and subsequent land speculation has been the major cause of deforestation since the 1960s. In much of Central America, forests were converted to pasture for cattle to feed beef for the fast food industry in North America and Europe, the so-called hamburger connection. Banana plantations have been another major cause of deforestation in Central America. An important factor in deforestation in many areas of Southeast Asia and elsewhere is the alienation of local communities from their land and resources by state government. Forests have been converted to monocrop plantations of eucalyptus and other fast-growing trees for export to Japan and elsewhere to supply the paper pulp industry. In South and Southeast Asia rubber tree plantations have been another economic development destroying biodiversity.

Aquaculture is yet another kind of commercial and industrial farming, now producing a third of the fish consumed by humans. Fish farming has been destroying hundreds of thousands of acres of mangrove forests and other wetlands with their biodiversity in recent decades. Shrimp pond farms along the southern peninsula of Thailand have grown exponentially with the investment of outside capital and technology, with the benefits going mostly to outsiders. Although aquaculture is a very ancient, productive, and efficient method for producing quality protein in many parts of Asia and elsewhere, where it has traditionally been sustainable and integrated with other aspects of the economy and ecology, this new economic development is very different. The shrimp are usually much too expensive to be consumed by most local people. Instead, they are exported to distant markets in Japan, Taiwan, North America, and Europe. Yet shrimp ponds are short-lived because waste products accumulate in the sediments until they become toxic to the shrimp or for any other subsequent uses. Consequently, repeatedly aging ponds are abandoned and new ones are constructed. At the same time, this cancerous growth of shrimp farms is degrading and destroying the local economies and biodiversity of many coastal regions. Nevertheless, aquaculture is expanding as a response to the decline of ocean fisheries, and often, although not always, with deleterious environmental consequences.

Biodiversity Toxicification

Industry

At least since 1962, with the publication of Carson (1962)'s classic book *Silent Spring*, there has been growing concern about the environmental impact of chemicals and pollution. Because in both ecosystems and the biosphere, ultimately everything is connected to everything else in various ways and degrees, chemicals from agriculture, factories, motor vehicles, and other sources eventually circulate worldwide. Residues of dichlorodiphenyltrichloroethane (DDT) and other pollutants are even found deposited in layers of polar ice and the tissues of marine animals. DDT is still produced in China and India. In the Gulf of Mexico and other areas of the world's oceans, more than 50 dead zones from pollution and other causes have been recognized so far. The accumulation of nitrates and other nutrients from agricultural and household chemicals can generate the explosive growth of algae in lakes and rivers to the detriment of biodiversity, a process called eutrophication. Massive kills of birds, fish, and other species have been reported from this and other contaminants such as oil spills.

One recent possible symptom of widespread pollution, whether direct through water and soil contamination or indirect through increased ultraviolet radiation from the ozone hole, may be the gross deformities observed in frogs, a most alarming phenomenon and perhaps an early warning of impending ecological catastrophe. Pollution may be a direct or indirect factor in the alarming decline recently of bee, bat, and reptile populations. Another result of atmospheric pollutants such as motor vehicle exhaust is the greenhouse effect, which in the twenty-first century is increasingly recognized as a major cause of global climate change and the consequent rise of sea level by up to 2 m or more. The consequences of sea level rise on the biodiversity of coastal and marine ecosystems like wetlands and coral reefs are uncertain, but are likely to be negative and potentially catastrophic. In terms of high biodiversity, coral reefs are the marine analog of tropical rain forests. Global climate change is disrupting ecosystems and biodiversity throughout the planet.

Oil

Industrial society, whose lifeblood is oil and other fossil fuels that are actually the remains of ancient biodiversity, has produced unprecedented types and levels of chemical pollution that undoubtedly endanger and erode living biodiversity. To illustrate, in recent decades many remaining frontier zones like the Amazon of Ecuador and Peru have been one target for increasing oil exploration and extraction. Because of the isolation of these frontiers, the usual environmental safeguards and measures for clean-up are ignored.

During the exploration phase, hundreds of miles of roads and large grids of extensive trails for seismic testing are cut into the forest. The seismic explosions not only scatter wildlife, but also the resulting shock waves can kill hundreds of fish in rivers, lakes, and wetlands. During the production phase, a single oil well platform consumes about six acres of forest and about 2000 trees. (In the rain forest a single giant tree may be inhabited by thousands of insect and other

species, most unknown to science.) Adjacent production wastes and treatment chemicals amount to millions of gallons every day for decades. At well sites there is no proper disposal of toxic waste, only open-air pits that eventually overflow into the soils, ground waters, and surface waters, thereby contaminating and killing fish and other wildlife. One gallon of oil can kill the fish living in a million gallons of water and adversely affect aquatic life at concentrations as low as one part per hundred billion (Kimerling, 1991).

Over decades, many hundreds of oil wells and extensive pipelines allow for numerous leaks and spills of black crude when breaks occur through metal aging or earthquakes. The magnitude of pollution that has been occurring in frontiers like the Amazon makes the oil spills associated with the Exxon Valdez, Gulf War, and Deepwater Horizon look like minor irritants in comparison! The costs to biodiversity are incalculable. Furthermore, beyond the corporate irresponsibility and massive environmental destruction, in the Amazon, oil is even being pursued in wildlife reserves and other areas supposedly set aside for conservation by national governments.

Militarization

A grossly neglected type of human impact on biodiversity and the environment are military activities and warfare, even though armament production is the top industry in the world with more than \$400 billion in sales annually (Stockholm International Peace Research Institute (SIPRI), 2011). One aspect of warfare that is especially detrimental to biodiversity is the use of scorched earth tactics, which unfortunately are nothing new. One of the largest applications of this tactic was the US military's dumping of some 13 million gallons of Agent Orange to defoliate forests in the Vietnam War during 1962–1971. In recent decades, the US war on drug production in Amazon forests has also involved the use of defoliants. During the Gulf War, the government of Iraq set fire to oil wells in the desert of Kuwait and created oil spills along the coasts. The tolls of such tactics and other impacts of warfare and militarization on local and regional biodiversity have yet to be fully revealed. Yet as Hanson *et al.* (2009) note, "More than 90% of the major armed conflicts between 1950 and 2000 occurred within countries containing biodiversity hot-spots, and more than 80% took place directly within hotspot areas."

The rise of nationalism and ethnic conflicts with the end of the Cold War has spread militarization into frontier, border, and other zones. Conflicts and wars are likely to proliferate in the future, according to Malthusian pessimists and others who consider growing resource scarcity and competition as major contributing causes. Such situations will be aggravated by global climate change. If so, then national and international security would be well served by redirecting a significant portion of funds that now go to the weapons, military, and defense industries into biodiversity and environmental research, education, and conservation programs as well as sustainable economic development. A complication is the issue of parks versus people; that is, whether environmental conservation should concentrate on developing protected areas,

developing local economies that alleviate poverty and are sustainable, or somehow integrate these two concerns.

Whereas war may threaten and erode biodiversity, peace may promote it. For instance, the Demilitarized Zone (DMZ) between North Korea and South Korea is a corridor 4 km wide and 250 km long that extends across the peninsula. For about six decades this corridor has been rigidly enforced as a no-man's land. As a consequence, farmlands thousands of years old and degraded forests have both reverted to a natural condition, thus protecting threatened and endangered species of plants and animals, as well as a cross section of the ecosystems of the Korean peninsula (Kim, 1997). The international peace parks between Costa Rica and its neighbors, Panama and Nicaragua, also promote biodiversity conservation by acting as refuges from most human activities.

Anthropocene

The human impact on the planet has reached such a threshold that geologists are now considering declaring a new epoch, the Anthropocene, as the age of human domination. It began two centuries ago with the Industrial Revolution at the end of the previous Holocene epoch from 10,000 to 12,000 years ago. It reflects the increasing visibility of the impact of humankind as a whole on the geology and ecology of the planet, but recognizes the seminal importance of industrialization. The human population explosion is another major contributing factor and has even been compared with cancerous growth (Hern, 1993). During the Anthropocene the impacts of the population and economic explosions, the latter including per capita consumption of natural resources and production of waste, involve urbanization; combustion and depletion of fossil fuels; increased emissions of gases like carbon dioxide, sulfur dioxide, nitric oxide, and methane; substantial alteration of the biogeochemical cycles and of biophysical landscapes; construction of megadams; rampant deforestation; spreading desertification; increased soil erosion and sedimentation rates silting waterways; depletion of freshwater and marine fisheries; mass extinction; and so on (Myers and Kent, 2005).

During the Anthropocene the global geological, climatic, and ecological impacts of *H. sapiens* are of such a magnitude as to be qualitatively distinct from anything prior to the Industrial Revolution. For instance, geologically, some human impacts are of a magnitude similar to earthquakes and volcanic eruptions. Increasingly there are anthropogenic ecosystems that depend on human activities for their creation and maintenance such as various types of rangelands, croplands, managed forests, and dense settlements. However, there is a continuum from natural to anthropogenic biomes and ecosystems, and many landscapes are a heterogeneous mosaic between these two poles instead of one or the other extreme, this mosaic now covering about 75% of the land surface of the planet.

Global climate change is well underway and increasingly threatens biodiversity. It is a serious challenge to protected areas as well as other environments. Populations, species, and ecosystems are already responding in various ways. Many species of plants are adjusting the timing of their life histories (phenology) whereas many species of animals are adapting the timing in their life cycles. The migration patterns and

geographic distribution of species are changing (Lovejoy, 2010). Moreover, some estimate that more than a third of all species may become extinct as a result of global climate change (Thomas *et al.*, 2004).

The Anthropocene refers mostly to the total human impact when viewed cumulatively since the beginning of industrialization and collectively throughout the world. The possibility of somehow altering the character, scale, and intensity of population growth, industrialization, resource consumption, pollution, economic development, and related factors to significantly reduce their detrimental impact on biodiversity and other environmental phenomena would appear to be rather doubtful, at least in the short term. Yet the human economy depends on the nature's economy including its ecosystem services. In the long term, if radical transformations to more sustainable and greener lifestyles and societies are not achieved, then it may well be ecocidal for the Earth and suicidal for humanity. If the human species can significantly alter the chemistry of the atmosphere and oceans, then surely it can alter its own behavior, if for no other reason than for the sake of its own survival and well-being. However, dangerous short-term economic and political interests as well as just plain ignorance or denial are major obstacles.

Biodiversity Futures

The Uncertain Future

As those from the green sociopolitical movement and many others recognize, industrial society, capitalism, and economic development are based on the false assumption that infinite growth is possible on a finite base. Here growth refers to both population and economy. Base refers essentially to carrying capacity. The latter involves not only the ability of the land and natural resources to support a certain level of population without essentially irreversible resource depletion and environmental degradation, but also the capacity of ecosystems and the planet as a whole to absorb pollution and other anthropogenic stresses. Increasingly human impacts exceed the resilience of nature to regenerate and recover within a normal time span from any perturbations and stresses, natural or anthropogenic.

Until the demonstrably ecocidal ideas and practices of modern industrial society and related factors are corrected and ecosanity with some modicum of ecological balance is restored, the net impact of humans on biodiversity will be negative and only accelerate and intensify. Accordingly, all life, including that of humanity, will remain endangered. There is not much room for optimism, at least in the near future, given the great momentum of population and economic growth combined with political pressures for the so-called economic development and the elevation of the standard of living throughout the world, all at the expense of the environment and its natural capital of resources, biodiversity, and ecosystem services. Indeed, the ozone hole, acid rain, acidification of the oceans, collapse of oceanic and freshwater fisheries, destruction of coral reefs, soil erosion, desertification, global climate change, and other environmental problems from the local to global levels may be symptoms of the failure of the

experiment of industrial society after just two centuries. No human society is infallible and eternal – the archeological and historical records provide numerous cases of those that became maladaptive, collapsed, and disintegrated, such as Harappa in the Indus Valley, or ancient Greece and Rome, although the exact causes of some like Rapa Nui (Easter Island) are disputed.

Limits of Government

Regional, national, and international governmental and nongovernmental agencies have been making some significant progress on resolving environmental problems and managing the human impact on biodiversity, such as in the implementation of the Convention on Biodiversity in 1993 and the launch of the United Nations Decade on Biodiversity in 2011. Nevertheless, there are, for example, many serious limitations on the efficacy of government-protected areas for biodiversity conservation. First, estimates are they comprise up to 12% of the Earth's surface, which is not a very large or representative sample of the tremendous biodiversity of the planet. Second, many are little more than “paper parks” because of inadequate funding, staff, and administration. Third, they will come under increasing attack in many ways with accelerating population and economic pressure in the future. Fourth, even for some 100,000 areas that are supposedly protected by governments, only a fraction of these have been thoroughly inventoried for biodiversity, and it would take the equivalent of the current number of experts several centuries to inventory the remainder. Clearly there are enormous challenges for inventorying, managing, and conserving biodiversity (Myers and Kent, 2005; Naughton-Treves *et al.*, 2005).

Indigenous and other local communities can make a significant contribution to biodiversity studies and conservation, and thereby also have a positive impact on biodiversity. This is just beginning to be appreciated; an example is INBio (Instituto Nacional de Biodiversidad), the biodiversity inventory and conservation program in Costa Rica that employs local people as parataxonomists. Also, though today there are some 1600 botanic gardens in the world that help conserve plant diversity *ex situ*, there are nearly 7000 distinct cultures in the world and each may somehow contribute to *ex situ* and *in situ* conservation. Comanagement is usually the ideal, that is, the cooperative sharing between community and government in the design, authority, responsibility, and benefits of natural resource management and biodiversity conservation projects. Among the successes in comanagement are Manu National Park in the Peruvian Amazon and Kakadu National Park in northern Australia. However, when government administrators of protected areas ignore the needs of local people, then conservation efforts usually falter or fail.

Numerous people have grown increasingly skeptical that government, science, technology, education, economic, and other secular approaches are sufficient for resolving the spiraling environmental crises facing the world. They view such attempts as treating only the superficial symptoms of the crises, not the broader underlying causes. Some of these people are turning to their own religion as a source of worldviews, inspiration, motivation, attitudes, and values

for developing a more sustainable and meaningful relationship with nature (Dudley, Higgins-Zogib, and Mansourian, 2005, 2009). As the pioneers in spiritual ecology, indigenes can also provide profound insights for such endeavors (Sponsel, 2012).

Indigenous Potential

Indigenous cultures contrast sharply with ecocidal industrial and other modern cultures. Many indigenous societies, especially those that are more traditional, may provide heuristic models for biodiversity conservation through their intimate environmental knowledge (ethnoecology), sustainable economy, natural resource management and conservation practices, spiritual ecology, and protection of sacred places. (To a large extent this is because most indigenes lie to the left on the continua described in Table 1.) In these and other respects, it could be argued that many indigenous societies are actually more developed than industrial ones.

Regarding traditional environmental knowledge (TEK), for instance, the Ka'apor people in the Brazilian Amazon recognize at least 768 species of plants from seed to reproductive adult stages. This reflects a tremendous amount and depth of reliable empirical knowledge about the biodiversity in their habitat, and that example is just in their domain of useful plants (Balée, 1994). Indeed, such knowledge of indigenous and other peoples may provide biologists and conservationists with one desperately needed short-cut for the inventory and conservation of local biodiversity (e.g., Ventocilla *et al.*, 1995).

Indigenes often consider their environment, including the biotic and abiotic components, to be sacred in various ways and degrees. Such a worldview can encompass a deep respect and reverence for nature that tempers their cultural ecology and resource use, and that may lead to environmental conservation, inadvertently if not intentionally. The role of spiritual ecology and sacred places in biodiversity conservation is just beginning to be recognized and explored by those who have an open mind to such phenomena (Posey, 1999).

Most indigenous and numerous other religions are nature centered, considering certain areas of nature in their habitat to be the foci of spiritual forces and beings. These sacred places are treated with extraordinary care and respect, and frequently taboos restricting resource use are associated with them. However, throughout the world, aggressive Christian missionization and other dominating monotheistic religions have often destroyed sacred places and indigenous religions because they were perceived as Pagan; these religion-inspired actions threaten and erode biodiversity as well. The objectification and commodification of nature also degrade and destroy sacred places, as Australian Aborigines and other indigenes have found with Western mining activities. Nevertheless, numerous and diverse sacred places in nature remain and may have contributed to biodiversity conservation in the past or could do so in the future (Ramakrishnan *et al.*, 1998).

Conservationists or Exterminators

The preceding discussion does not support the romantic idea that all indigenes are always in perfect harmony with their

environment, the myth of the so-called “ecologically noble savage,” which amounts to little more than a “straw man” argument (Harkin and Lewis, 2007). Instead, it recognizes the fact that many indigenous societies were to some degree environmentally friendly and that some still are, even though others are not or were not. These variants of the human impact on biodiversity have been documented in numerous cases by cultural and historical ecologists. Revisionist advocates who attack indigenous societies as environmentally destructive have yet to realize, let alone adequately resolve, the basic contradiction in their argument – how indigenes can be so knowledgeable about their habitat and interact with and monitor it on a daily basis, yet be so ignorant of, or amenable to, such destructive practices.

A related fallacy is that all humans are environmentally destructive, the so-called “*Homo devastans*” or “humans as the exterminator species” view (Balée, 1998). Such simplistic either–or, all-or-nothing, always-or-never thinking is misleading at best, but it is a surprisingly common defect of advocates of this view. Blaming all of humankind for a negative impact on biodiversity is simply scientifically inaccurate, sloppy scholarship, and professionally irresponsible, one of the problems with the idea of humans as the dominant animal. It needs to be emphasized again that humanity is diverse and so is its impact on biodiversity – some societies decrease it, others sustain it, some enhance it, and others affect it in some combination of these directions. A more careful, contextualized, and nuanced approach to such issues is sorely needed.

Diversity Principle

In general, several authorities have observed independently that the greatest concentrations of biological diversity tend to coincide with those of cultural diversity, especially in tropical forest areas, and most of all in the so-called megadiversity countries of Brazil, Colombia, Mexico, Congo, Madagascar, Indonesia, and Papua New Guinea. The present author calls this general tendency toward a geographical coincidence of high cultural diversity and high biodiversity the *diversity principle*. This coincidence has only begun to be recognized and explored, let alone explained. However, wherever indigenous societies thrive, biodiversity is likely to do so as well.

One thing is certain: in such megadiversity regions, threats to either cultural or biological diversity also threaten the other. Ironically, many indigenous societies that have proven sustainable and adaptive for centuries or even millennia, as well as their environments, are being degraded and destroyed by industrial and other societies that have yet to stand the test of time and increasingly show clear symptoms of maladaptation. The concerns for biodiversity conservation and human rights are interdependent. Furthermore, the degradation and destruction of cultural diversity, like that of biodiversity, seriously endanger the future adaptability of *H. sapiens* as well as biological evolution in general (Maffi, 2001; Maffi and Woodley, 2010).

Conclusions

Globally the net impact of the human species has decreased biodiversity. However, not all humans are equal in their

impact on biodiversity because of the tremendous diversity in humankind throughout its temporal and spatial distributions, including cultural diversity. At the population level, clearly some societies may sustain or even enhance biodiversity. In particular, many indigenous societies, especially those who retain some core traditions despite superficial changes, have special potential in their environmental knowledge, world-views, values, and other attributes to contribute to developing systems for the sustainable use, management, and conservation of biodiversity. The cumulative and collective impact of humans on biodiversity across the world is sufficient to make it imperative that anyone concerned with the biodiversity of any area must consider the possibilities of human influence. Accordingly, research on cultural ecology and historical ecology is usually indispensable.

Current anthropogenic extinction rates are estimated at 1000 to 10,000 times higher than normal background rates. Furthermore, these recent anthropogenic extinctions also involve plants, whereas prehistoric mass extinctions mainly affected animals. This is an alarming fact, among other reasons, considering how fundamental plants are to other life as primary producers in capturing solar energy through photosynthesis. Another distinction of the present extinction spasm is that an increasing proportion of humanity is becoming aware of what they are doing to nature and could change their behavior to reduce their negative impacts. After all, destroying biodiversity and ecosystems is ultimately ecocidal for humanity since they are our life-support systems.

Biodiversity is unlikely to be adequately conserved only by preservationism – by isolating nature from human disturbance in a few areas of supposed wilderness. Much more effort needs to be directed to adequately recognizing and better managing human impacts from the local to the global levels and over the long term. One problem is that decisions and actions that seem reasonable in the short term may have negative consequences in the long term. Thus, adequate environmental and resource management requires, among other things, much better informed politicians and policymakers at all levels from the local to the international who have the political will and morality to consider no less than the integral relationship between humanity and biodiversity for many generations to come. Of course, so far such leadership is grossly inadequate, but not unprecedented. For instance, the Iroquois in North America acted with the seventh generation into the future in mind. Perhaps the Convention on Biological Diversity from the 1992 Rio Summit, Rio + 10, the Earth Charter, and other initiatives are a hopeful change.

Biodiversity conservation also depends on a much more informed, concerned, and involved public that understands the nature and consequences of human impact on biodiversity. Considering the gravity and urgency of this subject, environmental and biodiversity education must be advanced at all levels including in the mass media. In the process, environmental ethics must be first and foremost. One of the best places to begin is by exploring Aldo Leopold’s (1949) land ethic: “A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise.” (However, today the term “resilience” is more appropriate than “stability.”) Every individual decision potentially has some impact on biodiversity, however

small or indirect; and those of humanity collectively can be synergetic and life threatening.

Finally, because the human impact on biodiversity both locally and regionally is mixed with positive as well as negative influences, there is reason for hope as well as despair for the future. However, with the current magnitude of biodiversity loss and other environmental problems, there is no doubt that the very viability, resilience, and habitability of too many of the world's ecosystems, and thereby the biosphere as a whole, are at risk, as are the very futures of organic and human evolution on this planet. Globally the net impact of *H. sapiens* in reducing biodiversity is a dangerous reversal of the megatrends that held throughout the past 3.75 billion years of organic evolution on Earth – namely increasing diversity, complexity, and adaptability. Furthermore, recovery from this extinction spasm may require thousands or even millions of years (Weisman, 2007). Because of the gravity and urgency of the negative impact of humans on the Earth's life, it is perhaps the single greatest challenge facing humankind and biodiversity studies for the twenty-first century.

Hunter-Gatherer Societies, Ecological Impact of

Kathleen A Galvin and Tyler Beeton, Colorado State University, Fort Collins, CO, USA

© 2013 Elsevier Inc. All rights reserved.

This article is a revision of the previous edition article by Kathleen A. Galvin, volume 3, pp 411–415, © 2001, Elsevier Inc.

Glossary

Bands The basic economic, social, and political unit of hunter-gatherer societies.

Cultural change The process by which cultures undergo change in response to social, political, and environmental factors.

Cultures and the global system The analysis of cultural diversity, responses and adaptations of smaller scale societies to emerging global trends.

Exogamy The practice of a person seeking a mate outside of his or her group.

Global environmental sustainability The effect of human social systems and economies on ecosystem processes, their feedbacks, now and into the future.

Human environment interactions The study of the complex systems of interaction between people and their environment.

Patrilocal residence The practice of married couple living in the husband's community.

Introduction

Many people have impressions of hunter-gatherers as people who live in harmony with nature, who are organized into simple societies, and are associated with our “pristine” Paleolithic hunter-gatherer past. Many of these stereotypic impressions are false (cf. Moran, 1991; Cane, 1996). Today, all foragers live in nation-states, have some dependence on either crop cultivation or wage labor, and are not isolated. Hunter-gatherer societies have social systems that are extremely complex and whose interactions with the biodiversity surrounding them are as complicated and variable as was probably the case 10,000 years ago when all humans were foragers. It is no accident that today, areas with the greatest remaining biodiversity are also the areas inhabited by hunter-gatherers. Many hunter-gatherers retreating from land appropriation, settler immigration, and European diseases have occupied the most remote parts of their region. Today, these homelands are often part of or adjacent to conservation areas, parks, or other protected areas.

This article describes traditional hunter-gatherer societies and the adaptations these societies have made to the environment. As hunter-gatherer societies and their environments have undergone continuing changes, issues of biodiversity conservation and hunter-gatherer welfare are discussed within the context of their changing world.

Hunter-Gatherer Societies and Natural Resource Exploitation

Because hunter-gatherers have lived in diverse environments and live next to numerous other cultural groups, they have manifested an incredible diversity of cultures and natural resource-management adaptations. Nevertheless, there are several general characteristics of hunter-gatherer societies: these traits have had a direct impact on the use of natural resources.

Traditional hunter-gatherer societies were comprised of bands, social groups made up of close biological kin and friends. The composition and sizes of bands changed seasonally, depending on the abundance and location of food resources. Bands were led by individual hunters who were respected for particular talents such as singing or dancing well, good storytelling, or hunting prowess. Other features of band organization are small group size, flexible but primarily patrilocal residence, and strong pair bonds between individual men and women. Marriage was exogamous, that is, females were recruited from other groups. These features of hunter-gatherer society were a reflection of a history of ecologic, economic, and social interactions. For example, Efe Pygmy hunter-gatherer men of the Ituri Forest in the former Zaire had very strong relationships with close kin, which facilitated defense of their territories against other cooperative kin groups (Bailey and Aunger, 1989). Moreover, related men could assure women access to valuable resources in neighboring Lese agricultural villages. Also, women were attracted to men who could guarantee long-standing reciprocal economic relationships with Lese villages. Competition for women was high, so close relations with kin may also have helped to obtain marriageable women and provide protection, as some women left Efe society to live in Lese agricultural villages.

Hunter-gatherers were sedentary or nomadic depending on the distribution and dynamics of their resource base and their economic relations with other people. Typically, men hunted and fished while women gathered and collected foods. Sometimes women's work contributed more to the diet and sometimes male hunting and fishing products were most important. Gathering of wild foods tended to contribute more to the diet among people inhabiting tropical and semitropical areas (e.g., Bushmen of the Kalahari) than in northern temperate climates (e.g., the Inuit of Canada) where hunting contributes the bulk of the diet. Staple foods were exchanged with neighbors and more recently in markets (Moran, 1991).

Foragers learned about their environment and resource use through acculturation. Parents taught their children different kinds of ecological knowledge and resource-exploitation strategies. Ecological knowledge is a source of landscape manipulation. For example, the Kayapo Indians of Brazil created forest islands of planted semidomesticated crops of medicinal species, wild yams, and bush bean, as well as domesticated plants such as taro, papaya, and banana (Posey, 1985). A fully grown island had sites that varied in shade and moisture, thereby creating the opportunity for cultivation of different crops. They became, through time, forest patches of varying successional stages within the savanna. Cree Indians of North America rotated their hunting and fishing lands yearly to reduce wildlife disturbance and increase harvests. Biodiversity conservation is, in this case, an indirect effect of resource management. There is evidence that until recently, Indians of Canada used fire to maintain trails and to open up meadows (Lewis, 1989). This provided improved habitat for ungulates and increased hunting success. Australian aborigines used fire to clear trails (of poisonous snakes) and keep game habitat open.

Appropriate use of natural resources was maintained through moral and belief systems of forager societies, which included a strong respect for nature. Through religious belief and social conventions, people revered and exerted some control over their natural resources. These beliefs, however, did not always prevent hunter-gatherers from overusing their resource base. Hunter-gatherers did not always live harmoniously with the environment. Indeed, evidence of escalating overuse is accumulating (e.g., Redford and Mansour, 1996; Lyman, 2003).

Conservation among Hunter-Gatherers

It has been suggested that hunter-gatherer adaptation occurred in environments where resources were freely available to all and were abundant. Thus, the environment was one where subsistence strategies emphasized short-term returns over long-term conservation. But during the Neolithic rise of agriculture, natural ecosystems were compressed and the value of resources increased as relative abundance declined. Some scholars have suggested that self-regulatory mechanisms evolved under resource limitation in some hunter-gatherer societies (Berkas and Folke, 1998).

There has been much written about how hunter-gatherers are actively engaged in conserving resources, especially animal resources. However, the actual data gathered on the subject suggest that subsistence hunters do not conserve prey resources. Most work shows that hunters are concerned about short-term gains and not about resource conservation (Smith and Wishnie, 2000). Small, mobile groups may use resources in a sustainable manner, for example, by maintaining small groups and ranging over a large territory, but this does not necessarily imply that they are consciously conserving resources. Evidence suggests that some resources may be used intensively or even depleted in local areas while other resources are sparingly used. For example, Alvard (1998) showed that the Piro hunters of Peru depleted the large primates in the area around their village but have not yet done so to peccaries. Likewise he showed that the Indonesian Wana

nearly depleted their area of macaques (large primates) but hunt pigs in a sustainable manner. Overexploitation of bushmeat in Mozambique (Fusari and Carpaneto, 2006) and in Gabon (Carpaneto *et al.*, 2007) is leading to resource depression of certain species. These and other studies (e.g., among the Inuit of Canada, the Ache of Paraguay, and the Cree of Canada) show that both overexploitation and conservation may be practiced by hunting groups. But the point remains that hunters sometimes reduce prey species to the point of local extinction.

One plausible explanation for resource depletion is that the resources exploited by subsistence hunters are considered to be open-access resources. Open access implies that there are no controls over resource use, which is said to result in the "tragedy of the commons" (Hardin, 1968; National Research Council (NRC), 2002). This concept proposed that deterioration of open-access grazing land is inevitable when individuals see no benefits from resource conservation. Another reason for resource depletion is lack of concern for very abundant resources. Some level of scarcity adds value to a resource relative to when resources are quite abundant. Resource users are motivated to conserve only when they see benefits to nonuse of resources. Thus, it is only when long-term benefits outweigh the short-term benefits that conservation is expected. When tied to a specific resource base and well-defined territories, hunter-gatherers have long-term strategies for natural resource conservation (Alvard, 1998; Arunato, 2006). For example, traditional Maine lobstermen have had strong norms of territory ownership, which are enforced through threats of violence and damage to property.

Although foragers may or may not overuse resources, their perception of the land and its value is based on use rights. Local biological diversity is an important element of local survival strategies. This view contrasts with the western view of biodiversity conservation, which is based on Western epistemology. In the western view, nature exists apart from humankind and has value independent of human use. Biodiversity conservation implies no resource use or restraints in resource use.

Processes of Modernization and Hunter-Gatherers

Major changes in hunter-gatherer societies are occurring even in the most remote regions of the world. It is even questionable whether or not hunting and gathering exists today as a distinct economic occupation. These changes are associated with human population growth, land-tenure changes, land-use changes such as agricultural development, infrastructure advancement, resettlement schemes, tree harvesting, mining, and oil exploration, and other types of development. The building of roads makes it easier for outsiders to gain access to remote areas and the resources therein. In addition, hunter-gatherer populations are growing, altering their relationship to the land. The result is that indigenous systems of resource use are changing due to both internal and external pressures. The traditional systems of resource use are not sufficient or are sometimes less effective under current conditions. For example, traditional sanctions to protect, or at least not exhaust, resources are becoming ineffectual as cash income has become increasingly important to individuals interested in cash and

commodities. Hunter-gatherers now have, under these conditions, a growing demand for cash and market goods. Under these conditions, it is less likely that people will give priority to conservation unless it is economically profitable (Daily *et al.*, 2000)

Land Tenure, Institutions, and Biodiversity

One political factor that is almost universally common among hunter-gatherers today is that they often do not own or have control of the land they live on. Until recently, their remoteness meant that they and the resources on which they depended were somewhat protected from outside influences. Thus, resources were locally controlled by informal norms through individual behavior. Now, however, national governments and private entrepreneurs, among others, have put native lands to “productive” use. This means that if the market for some product is strong, it will be exploited or cultivated regardless of environmental impact (Lambin *et al.*, 2001). For example, the strong local demand for *aguaja* (a local plant) in the Peruvian Amazon has led to destructive harvesting. In theory, most hunter-gatherer communities have use rights to their territories but old laws and treaties are continually violated. Legalizing communal resource-use rights is a way of giving hunter-gatherers a long-term stake in conserving the resources on which they depend. Securing rights to resources can occur through various management and development institutions. This means that hunter-gatherers, who formally did not have institutions for collective action in the formal sense, find the need to work with formal western institutions to acquire control over their lands.

The future of biodiversity, conservation, and hunter-gatherer sustainability depends on understanding that there are fundamental differences in the concept of conservation for westerners and for indigenous hunter-gatherers, though this too is changing. Understanding that there are different worldviews toward nature is fundamental to forming a relationship between conservation groups and hunter-gatherer peoples. The reality is that even if hunter-gatherers are using resources, selling wild animals, and cutting down trees, they perhaps remain the most effective conservationists for their region. Therefore, acceptance that there are different ways of knowing the world is a first prerequisite to working with indigenous hunter-gatherer populations. Second, it is necessary to recognize that there are no “pristine” hunter-gatherers and they have needs and aspirations just like the rest of us. Third, securing land tenure for hunter-gatherers and biodiversity conservation is required as a basis of a “sustainable” interaction.

Economic Development and Biodiversity Conservation

Community-based conservation is a concept aimed at involving local people in the conservation of wildlife or protection of biodiversity. The concept developed from the realization that much of the planet’s wildlife and biodiversity exist outside protected areas and in regions occupied by rural people in developing countries (Galvin *et al.*, 2008). Models of

community-based conservation adhere to the notion that if local communities can derive some value, nominal income, through conserving biodiversity, they will do so. This promising concept has been widely promoted as “the answer” to conservation in developing countries. Thus, several models of community-based conservation have developed (Goldman, 2003; Berkes, 2007) such as Integrated Conservation–Development projects. However, results from community-based conservation projects suggest that there are more failures than successes (Goldman, 2003; Berkes, 2004). Many community-based conservation efforts involve local communities in name only. Locals are neither involved in project identification and planning, nor are they beneficiaries; thus, these projects are not really community-based conservation projects. Other scenarios for failure also have in common insufficient involvement of the local people at all levels in the project. For community-based conservation to work, people need to be considered a component of the system being conserved and brought into the project process from the beginning (Carlson and Berkes, 2005; Reid *et al.*, 2009).

It Is Useful to View Hunter-Gatherers and Biodiversity as a Social–Ecological System

One of the fundamental problems with community-based conservation is that hunter-gatherers as well as other indigenous populations are often viewed as an external disturbance to the natural system rather than as integral components of the ecosystem. But hunter-gatherer societies see their relationship with the environment as one: they are part of that environment. Though not a study on foragers, but rather herders who do some hunting and gathering, the South Turkana Ecosystem Project (Ellis and Swift, 1988; Little and Leslie, 1999) is one of the only truly interdisciplinary and long-term projects to study the social behavior, knowledge systems, demography, human biology, and ecology of a group of people. An important goal of this study was to understand how the environment affected human management and how people affected the environment. In this case, people and livestock (camels, cattle, sheep, goats, and donkeys) lived in a harsh, dry, and highly seasonal environment. This assemblage of people, livestock, plants, and other organisms within a semiarid ecosystem produced a remarkably interactive system.

Vegetation structure in this tropical savanna and dry woodlands was shown to be hierarchically constrained by physical factors: by climate at regional scales, by topography and geomorphology at landscape scales, and by water redistribution and disturbance at local and patch scales; livestock and humans played a small role. The pastoralists did influence vegetation composition and cover by burning, woodcutting, and through seed distribution by livestock. These influences were small. Livestock ecology and production followed those of the seasonal dynamics of plants. The different patterns of forage utilization by different herbivores, plus differential habitat use, led to almost complete niche separation among this suite of domestic herbivores; among all five species, they managed to utilize a wide variety of the available plant types in the ecosystem. Thus, physical heterogeneity of the Turkana landscapes ultimately resulted in

spatial and temporal variation in plant production, plant life form diversity, and refuge areas for pastoralists. These, in turn, contributed to social and ecological persistence by reducing variability of ecosystem energy flow and long-term variations in species diversity. Thus, biodiversity was important to ecosystem (which included people) maintenance. These systems' approach to understanding human–environment interactions is a useful way to discern the ecological impact of hunter-gatherers and, more importantly, to derive appropriate management of lands where hunter-gatherers live.

The description presented here shows that indigenous concepts of conservation, ecological knowledge, and moral and religious beliefs are fundamental to understanding how hunter-gatherers use resources. Not all hunter-gatherers conserve their resources, thus whether or not and to what extent hunter-gatherers effect their environment is an empirical question that needs to be investigated, not a notion to be assumed one way or another. It is, however, the case that when hunter-gatherers have short-term strategies for resource use, they may overuse some resources; when long-term goals are in place, they may not. Informal institutions control use of some resources in hunter-gatherer societies, but collective action or formal institutions are generally not well developed. With major changes in and around the lands inhabited by hunter-gatherers, it is becoming increasingly necessary for hunter-gatherers to develop institutions to gain control over their resource base. Alliances between hunter-gatherers and others interested in conservation may facilitate resource-management strategies that reduce the impact of negative changes. Hunter-gatherer natural resource-management strategies that include their social system are important attributes of these social–ecological systems and need to be the fundamental components of any plan to conserve biodiversity.

Glossary

Bio-cultural axiom Recognition that biological and cultural diversity are mutually dependent and geographically coterminous.

Cultural diversity Variety of human groups distinguished through beliefs, lifeways, dress, food, languages, sexual behavior, forms of productive organization, art, and conceptions of nature.

Endemic languages Languages that are restricted to a single country and, like their species counterparts, hold a high percentage of the unique traits in human language.

Ethnoecology Interdisciplinary study that explores how nature is perceived by human groups through a screen of beliefs and knowledge and how humans, in terms of their images and symbols, use or manage natural resources. The above is synthesized by the complex formed by *kosmos*, *corpus*, and *praxis*.

Indigenous peoples Those who are the original or oldest inhabitants of an area or region, or who have lived in a traditional homeland for many generations, usually many centuries.

Outline

Indigenous people, who number more than 300 million, are inhabitants of practically every main biome of the earth and especially of the least disturbed terrestrial and aquatic ecosystems of the world. Based on an exhaustive review of published data, this article stresses the strategic importance of indigenous peoples in the maintenance and conservation of the world's biodiversity.

Introduction

As a word and concept, biodiversity originated in the field of conservation biology. However, as *Alcorn (1994)* states "...while proof of conservation success is ultimately biological, conservation itself is a social and political process, not a biological process. An assessment of conservation requires therefore an assessment of social and political institutions that contribute to, or threaten, conservation." One of the main social aspects related to biodiversity is, undoubtedly, the case of the world's indigenous peoples.

Scientific evidence shows that virtually every part of the planet has been inhabited, modified, and manipulated throughout human history. Although they appear untouched, many of the last tracts of wilderness are inhabited and have been so for millennia. Indigenous peoples live in and have special claims to territories that, in many cases, harbor exceptionally high levels of biodiversity. On a global basis, human cultural diversity is associated with the remaining concentrations of biodiversity. Both cultural diversity and biological diversity are endangered.

Given the above, this article offers a review about the multiple importance of indigenous peoples and makes the point that valuable, local-specific views, knowledge, and practices are used by indigenous peoples who have relied for hundreds or thousands of years on the maintenance of biodiversity. Indigenous peoples are often classified as impoverished or treated as invisible. However, in the final analysis,

they hold the key to successful biodiversity conservation in most of the biologically richest areas of the world.

Indigenous Peoples

Indigenous people number more than 300 million (*Table 1*). They live in about 75 of the world's 184 countries and are inhabitants of practically every main biome of the earth. Indigenous peoples, also called tribal, aboriginal, or autochthonous peoples, national minorities, or first peoples, are best defined by using several criteria. Indigenous peoples may have all or part of the following criteria: (1) are the descendants of the original inhabitants of a territory which has been overcome by conquest; (2) are "ecosystem peoples," such as shifting or permanent cultivators, herders, hunters and gatherers, fishers, and handicraft makers, who adopt a multiuse strategy of appropriation of nature; (3) practice a small-scale, labor-intensive form of rural production which produce little surplus and has low energy needs; (4) do not have centralized political institutions, organize their life at the level of

Table 1 Estimated numbers of the world's indigenous peoples

Region groups	Number of cultural group	Population
North America	250	3,500,000
Latin America and the Caribbean	800	43,000,000
Former Soviet Union	135	40,000,000
China and Japan	100	67,000,000
The Pacific	1273	2,000,000
Southeast Asia	900	30,000,000
South Asia	700	100,000,000
Australia and New Zealand	250	550,000
Africa	2010	50,000,000
Total	6418	336,050,000

Source: Reproduced from Burger J (1987) *Report from the Frontier: The State of the World's Indigenous Peoples*. London: Zed Books LTD, and Hitchcock (1994).

community, and make decisions on a consensus basis; (5) share a common language, religion, moral values, beliefs, clothing, and other identifying characteristics as well as a relationship to a particular territory; (6) have a different world-view, consisting of a custodial and nonmaterialist attitude to land and natural resources based on a symbolic interchange with the natural universe; (7) are subjugated by a dominant culture and society; and (8) consist of individuals who subjectively consider themselves to be indigenous.

It is possible to find indigenous peoples carrying out many different activities of use and management of the planet's ecosystems: As forest-dwellers in the tropical lowlands or in the mountains, pastoralists in savannas and other grasslands, or nomadic or semi-nomadic hunters and gatherers in forests, prairies and deserts. Fishing is, in addition, the principal economic activity and source of food for several million coastal and island dwellers, as well as many indigenous peoples inhabiting margins of rivers. Large numbers of indigenous peoples are, however, peasant producers and therefore can be indistinguishable from the nonindigenous peoples living nearby. In the Andean and Mesoamerican countries of Latin America, for instance, indigenous peoples farm like mestizo peasants. Similarly, in India distinctions between scheduled tribes and nontribal peoples cannot be made solely on the basis of productive activities. In these and many other cases, nonindigenous peasants and indigenous peoples produce the same crops with the same farming methods. Since in numberless countries many mestizo peasants are direct descendants of the indigenous peoples and retain most of their cultural traits, it has been pointed out that a broader definition of indigenous peoples might increase the real numbers. Thus, by considering other characteristics than language, it is possible to enlarge the number of indigenous peoples in the contemporary world. Given the above, some authors like Burger think that the number of indigenous people could double that previously estimated. Thus, in the contemporary world there may be as many as 600 million indigenous peoples. However, such figures need qualification.

Based on the percentage of total population identified as belonging to the indigenous peoples, it is possible to recognize a group of selected nations with a strong presence of these peoples: Papua New Guinea (77%), Bolivia (70%), Guatemala (47%), Peru (40%), Ecuador (38%), Myanmar (33%), Laos (30%), Mexico (12%), and New Zealand (12%). However, the absolute number of people recognized as indigenous allows identification of nations with high indigenous population such as India (more than 100 million) and China (between 60 and 80 million).

Biological Diversity and Diversity of Cultures

On a global basis, human cultural diversity is associated with the remaining concentrations of biodiversity. In fact, evidence exists of remarkable overlaps between global mappings of the world's areas of high biological richness and areas of high diversity of languages, the single best indicator of a distinct culture. The above correlation can be certified both on a country-by-country basis as well as using biogeographic criteria.

Measured by spoken language, the entire world's people belong to between 6000 and 7000 cultures. It is reported that 6700 of these are indigenous cultures. Thus, indigenous peoples account for as much as 80–90% of the world's cultural diversity. On the basis of the inventories done by linguists, we can draw up a list of the regions and countries with the greatest degree of cultural diversity in the world. According to Ethnologue, the best existing catalog of the world's languages, there is a total of 6703 languages (mostly oral), 32% of which are found in Asia, 30% in Africa, 19% in the Pacific, 15% in the Americas, and 3% in Europe (Gordon, 2005). Only 12 countries account for 54% of the human languages. These countries are Papua New Guinea, Indonesia, Nigeria, India, Australia, Mexico, Cameroon, Brazil, Zaire, Philippines, USA, and Vanuatu (Table 2).

However, according to an analysis of biodiversity on a country-by-country basis (Mittermeier and Goettsch-Mittermeier, 1997) there are, similarly, 12 countries which house the highest numbers of species and endemic species (Table 3). This assessment was based on the comparative analysis of eight main biological groups: mammals, birds, reptiles, amphibians, freshwater fishes, butterflies, tiger-beetles, and flowering plants. The nations considered as "megadiversity" countries are: Brazil, Indonesia, Colombia, Australia, Mexico, Madagascar, Peru, China, Philippines, India, Ecuador, and Venezuela (Table 3).

Thus, the relationship between cultural diversity and biological diversity stands out in global statistics: nine of the 12 main centers of cultural diversity (in terms of number of languages) are also in the roster of biological megadiversity nations and, reciprocally, nine of the countries with the highest species richness and endemism are also in the list of

Table 2 Top 25 countries by number of endemic languages

the 25 nations with the highest number of endemic languages (Tables 2 and 3).

The links between biological and cultural diversity can also be illustrated by using the data of the so-called Global 200, a program that the World Wide Fund for Nature (WWF) developed as a new strategy to identify conservation priorities based on an eco-regional approach. As part of this program, WWF has identified a list of 233 terrestrial, freshwater, and marine biological ecoregions representative of the Earth's richest diversity of species and habitats. A preliminary analysis conducted by the People and Conservation Unit of WWF of the presence of indigenous peoples in the 136 terrestrial ecoregions of Global 200, revealed interesting patterns (Oviedo *et al.*, 2000). As shown in Table 4, nearly 80% of the terrestrial ecoregions are inhabited by one or more indigenous peoples and half of the global estimated 3000 indigenous groups are inhabitants of these ecoregions. By geographical region, basically all the regions, except the Palearctic region, have 80% or more of their ecoregions inhabited by indigenous people (Table 4).

Biodiversity and Biomass Appropriation: The Role of Indigenous Peoples

Biodiversity conservation cannot be separated from natural resources use. Human appropriation of nature inflows minerals, water, solar energy, and principally living beings (biomass) from ecosystems. World statistics indicate that almost half the inhabitants of the planet are still people engaged in the appropriation of natural resources. This appropriation is carried out by a myriad of rural or primary producers through the management of terrestrial, marine, and freshwater ecosystems.

Forty percent of the total human population has been recorded by the Food and Agricultural Organization (FAO) as agricultural population (FAO, 2004). It can be estimated that between 60 and 80% of this agricultural population is represented by small-scale, solar-energized productive units based on a multiuse management of nature (Toledo and Barrera-Bassols, 2008). In fact, the statistical record shows that by 1999 around 1500 million rural people were practicing agricultural activities on areas of 5 ha or less. A similar pattern is found in the world's fisheries where more than 90% are small-scale, artesanal operators, acting in a great variety of coastal habitats.

Most of these small-scale farmers and fishers develop their production activities not as socially isolated households but as familial nuclei belonging to specific village communities, many of which, in turn, correspond to cultures that can be considered as indigenous. Moreover, within the core of these community-based producers, those identified as indigenous people are those who carry out the biomass extraction affecting at the lowest level of their local ecosystems. Called "ecosystem people" by some authors such as Dassman and Gadgil, these producers subsist by appropriating a diversity of biological resources from their immediate vicinity. Their quality of life is therefore intimately linked to the maintenance of certain levels of local biodiversity. As a consequence, they are productive actors in little transformed habitats of the world, including the main forest and sea dwellers, slash and burn agriculturalists, some 25–30 million nomadic herders or pastoralists (in East Africa, Sahel, and Arabian peninsula), most of the 15–21 million world fishers, and all the half a million hunters and gatherers who are still recognized as inhabitants of the contemporary world.

Table 4 Indigenous peoples in Global 200 terrestrial ecoregions considered priority areas by World Wildlife Fund for Nature

<i>Region</i>	<i>Ecoregions</i>	<i>Ecoregion with IP</i>	<i>%</i>	<i>Total IP in ecoregions</i>	<i>Number of IP in ecoregions</i>	<i>%</i>
World	136	108	79	3000	1445	48
Africa	32	25	78	983	414	42
Neotropic	31	25	81	470	230	51
Neartic	10	9	90	147	127	86
Asia and Pacific (Indo-Malayan)	24	21	88	298	225	76
Oceania	3	3	100	23	3	13
Palearctic	21	13	62	374	11	30
Australasia	15	12	80	315	335	65

Note: These figures, utilized by WWF International, underestimate the number of indigenous peoples given by several analysts. For example, Harmon (1996) reported a total of 5635 "endemic languages," which can be considered as socially equivalent to indigenous peoples. IP = Indigenous peoples.

In conclusion, indigenous peoples are the fraction of human appropriators of biomass determining the lowest ecological impacts. They generally live in what may be termed as "frontier lands" or "refuge regions;" thus remote areas of great wilderness where the structure, not the components, of original ecosystems remains more or less untouched. In many cases these lands and waters are untamed, unknown, unowned, and unclaimed.

Biodiversity and Indigenous People's Lands and Waters

Indigenous peoples occupy a substantial share of the world's little disturbed tropical and boreal forests, mountains, grasslands, tundra, and desert, along with large areas of the world's coasts and near-shore waters (including mangroves and coral reefs). The importance of indigenous territories to biodiversity conservation is therefore evident. In fact, indigenous peoples control, legally or not, immense areas of natural resources. Among the most remarkable examples are the cases of the Inuit people (formerly known as Eskimo) who govern a region covering one fifth of the territory of Canada (222 million hectares), the indigenous communities of Papua New Guinea whose lands represent 97% of the national territory, and the tribes of Australia with nearly 90 million hectares (Figure 1). Although numbering only above 250,000, the Indians of Brazil possess an area of more than 100 million hectares, mainly in the Amazon basin, distributed in 565 territories (Figure 2 and Table 5). Nearly 60% of the priority areas in central and southern Mexico recommended for protection are also inhabited by indigenous peoples (Figure 3), and half of

the 30,000 rural communities are distributed in the ten most biologically rich states of the Mexican territory. In summary, on the global scale it is estimated that the total area under indigenous control probably covers between 12% and 20% of the earth's land surface.

The best example of notable overlaps between indigenous peoples and biological rich areas is the case of tropical humid forests. In fact, there is a clear correspondence between areas of remaining tropical forests and the presence of indigenous peoples in Latin America, the Congo Basin in Africa, and several countries of tropical Asia such as Philippines, Indonesia, and New Guinea. The strong presence of indigenous peoples in Brazil, Indonesia, and Zaire alone, which accounts for 60% of all the tropical forest of the world, is remarkable.

In Latin America, this geographical relationship has been strikingly verified for the Central American countries by a National Geographic Society map produced by a project headed by Mac Chapin in 1992. The same pattern can be found in the tropical humid areas of Mexico inhabited by 1.6 million indigenous people, and for many regions of the Amazonia basin (see the case of Brazil in Figure 2). It has been estimated that in Amazonia, above one million indigenous people of eight countries possess more than 135 million hectares of tropical forest (Davis and Wali, 1994). Many temperate forests of the world also overlap with indigenous territories as, for example, in India (Figure 4), Myanmar, Nepal, Guatemala, the Andean countries (Ecuador, Peru, and Bolivia), and Canada.

However, more than two million islanders the South Pacific, most of who are indigenous peoples, continue fishing and harvesting marine resources in high biodiversity areas (such as coral reefs).

Biodiversity and Ethnoecology: Indigenous Views, Knowledge, and Practices

Biodiversity is a very wide concept that refers to the variety of landscapes, ecosystems, species, and genes, including their different functional processes. Therefore, maintenance and conservation of biodiversity demands efforts on these four levels. While the first level is oriented to preservation of

assemblies of "ecosystems," the second one focuses on protection of habitats in which the populations of species live.

At the species level, most knowledge on biodiversity concerns the large plants and animals such as flowering plants and vertebrates. The extent of diversity of smaller plants and animals remains to be inventoried and protected. While most biological diversity is constituted by wild plants and animals, an important subset involves the diversity among domesticated organisms. In this fourth level, the interest focuses on conservation of genetic variation of crops and domesticated animals. This section is dedicated to examining the potential role of indigenous peoples in biodiversity conservation from an ethnoecological perspective. Ethnoecology can be defined as an interdisciplinary approach exploring how nature is seen by human groups through a screen of beliefs and knowledge, and how humans, in terms of their images use or manage natural resources. Thus, by focusing on the *kosmos* (the belief system or cosmovision), the *corpus* (the whole repertory of knowledge or cognitive systems) and the *praxis* (the set of practices), ethnoecology offers an integrative approach to the study of the process of human appropriation of nature (Toledo, 2002). This approach allows recognition of the value of the belief-knowledge-practice complex of indigenous peoples in relation to the conservation of biodiversity.

The Kosmos

For indigenous peoples, land and in general nature, has a sacred quality which is almost absent from Western thinking (Berkes, 2008). Land is revered and respected and its inalienability is reflected in virtually every indigenous cosmovision. Indigenous peoples do not consider the land as merely an economic resource. Under indigenous cosmovisions, nature is the primary source of life that nourishes, supports, and teaches. Nature is, therefore, not only a productive source but the center of the universe, the core of culture, and the origin of ethnic identity. At the heart of this deep bond is the perception that all living and nonliving things and natural and social worlds are intrinsically linked (reciprocity principle). Of particular interest is the research done by several authors (Reichel-Dolmatoff, Boege, Ph. Descola, and van der Hammen) on the role played by the cosmology of several indigenous groups as a mechanism regulating the use and management of natural resources. In the indigenous cosmovision, each act of appropriation of nature must be negotiated with all the existing things (living and nonliving) through different mechanisms as agrarian rituals and shamanic acts (symbolic exchange). Humans are thus seen as a particular form of life participating in a wider community of living beings regulated by a single and totalizing set of rules of conduct.

The Corpus

Indigenous societies house a repertory of ecological knowledge which generally is local, collective, diachronic, and holistic. In fact, since indigenous peoples possess a very long history of resource-use practice, they have generated cognitive systems on their own circumscribed natural resources which

Figure 3 Geographical location of priority areas recommended by the Comisión Nacional para el Estudio y Uso de la Biodiversidad (CONABIO) of Mexico, overlapping with territories of indigenous communities. Note the high number of overlapping areas in the central and southern portion of Mexico, where most of the biological richness of the country is concentrated. Modified from CONABIO's map on priority areas for conservation, 1996.

are transmitted from generation to generation. The transmission of this knowledge is done through language, hence the corpus is generally an unwritten knowledge. Memory is, therefore, the most important intellectual resource among indigenous cultures.

This body of knowledge is the expression of a certain personal wisdom and, at the same time, of a collective creation, that is to say, a historical and cultural synthesis turned into reality in the mind of an individual producer. For this reason, the corpus contained in a single producer's mind expresses a repertoire that is a synthesis of information from at least four sources: (1) the experience accumulated over historical time and transmitted from generation to generation by a certain cultural group; (2) the experiences socially shared by the members of the same generation or cohort; (3) the experience shared in the household or the domestic group to which the individual

belongs; and (4) the personal experience, particular to each individual, achieved through the repetition of the annual cycles (natural and productive), enriched by the perceived variations and unpredictable conditions associated with them.

Thus, indigenous ecological knowledge is normally restricted to the immediate environments and is an intellectual construction resulting from a process of accumulation of experiences over both historical time and social space. These three main features of indigenous ecological knowledge (being local, diachronic, and collective) are complemented with a fourth characteristic, namely holistic. Indigenous knowledge is holistic because it is intricately linked to the practical needs of use and management of local ecosystems. Although indigenous knowledge is based on observations on a rather restricted geographic scale, it must provide detailed information on the whole scenery represented by the concrete

Figure 4 Geographical location of 20 indigenous groups (a), and principal forestry areas (b) of India. Although the long history of migrations of peoples makes it difficult to distinguish indigenous peoples in India, there are about 100 million people considered by the government as “scheduled tribes” speaking over 300 languages. These groups are generally residents of remote hilly or forested areas. Modified from *The State of India's Environment 1984–1985*.

landscapes where natural resources are used and managed. As a consequence, indigenous minds not only possess detailed information about species of plants, animals, fungi and some microorganisms; they also recognize types of minerals, soils, waters, snows, landforms, vegetations, and landscapes.

Similarly, indigenous knowledge is not restricted to the structural aspects of nature, which are related to the recognition and classification (ethnotaxonomies) of elements or components of nature, it also refers to dynamics (which refers to patterns and processes), relational (linked to relationships between or among natural elements or events) and utilitarian dimensions of natural resources. As a result, it is possible to integrate a cognitive matrix (Figure 5) which certifies the holistic character of indigenous knowledge and serves as a methodological framework to ethnoecological research (Toledo, 2002).

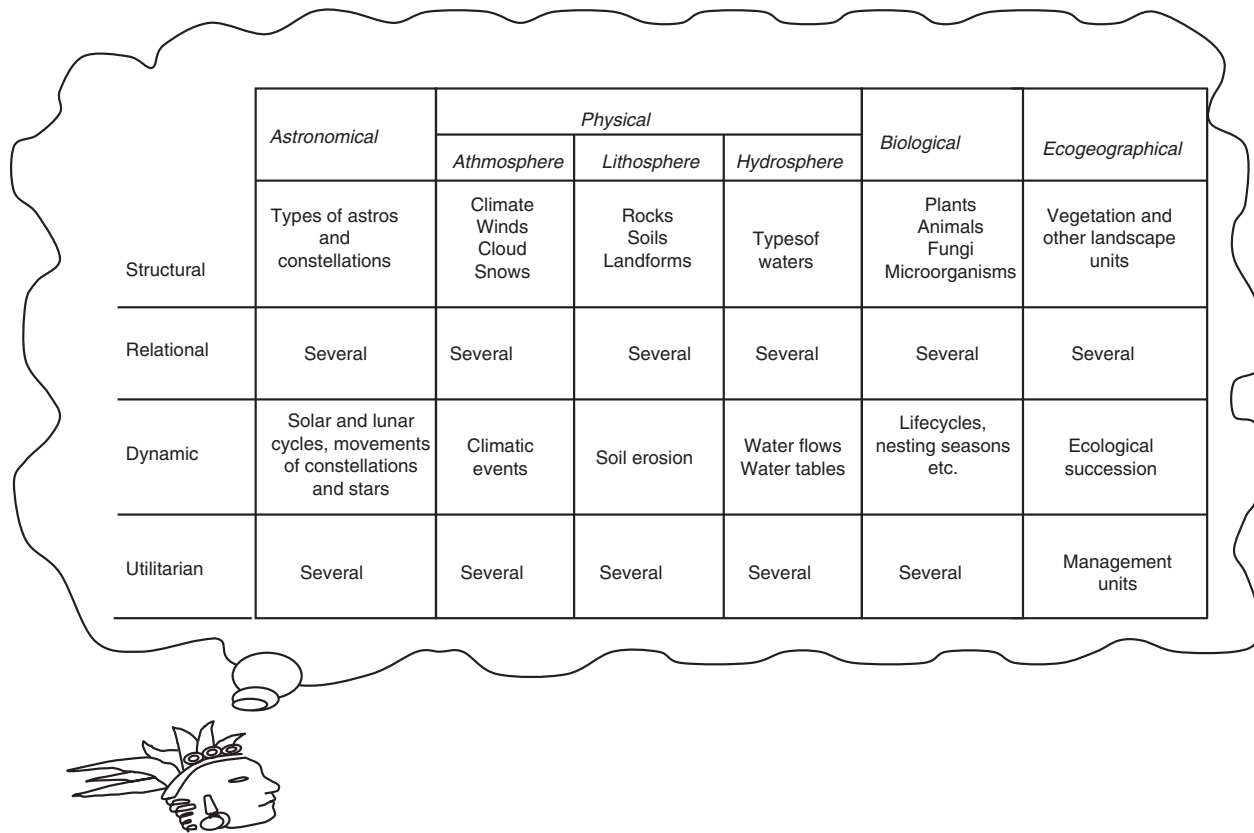

The Praxis

Indigenous societies generally subsist by appropriating a diversity of biological resources from their immediate vicinity. Thus, subsistence of indigenous peoples is based more on ecological exchanges (with nature) than on economic exchanges (with markets). They are therefore forced to adopt survival mechanisms that guarantee an uninterrupted flow of goods, materials, and energy from ecosystems. In this context a predominant use-value economic rationality is adopted, which in practical terms is represented by a multiuse strategy that maximizes the variety of goods produced in order to provide basic household requirements throughout the year (for further details on this strategy see Toledo, 1990). This

main feature accounts for the relatively high self-sufficiency of indigenous households and communities.

Indigenous households tend to carry out a nonspecialized production based on the principle of diversity of resources and practices. This mode of subsistence results in the maximum utilization of all the available landscapes of the surrounding environments, the recycling of materials, energy and wastes, the diversification of the products obtained from ecosystems and, especially, the integration of different practices: agriculture, gathering, forest extraction, agroforestry, fishing, hunting, small-scale cattle-raising, and handicrafts. As a result, indigenous subsistence implies the generation of a myriad of products including food, domestic and work instruments, housing materials, medicines, fuelwoods, fibers, animal forage, and others.

Under the multiuse strategy, indigenous producers manipulate the natural landscape in such a way that two main characteristics are maintained and favored: habitat patchiness, heterogeneity, and biological as well as generical variation. In the spatial dimension, indigenous people create a complex landscape mosaic in which agricultural fields, fallow areas, primary and secondary vegetation, household gardens, cattle-raising areas, and water bodies are all segments of the entire production system. This mosaic represents the field on which indigenous producers, as multiuse strategists, play the game of subsistence through the manipulation of ecological components and processes (including forest succession, life cycles, and movement of materials). It has been demonstrated that some natural disturbances can increase biodiversity if they increase habitat heterogeneity, reduce the influence of competitively dominant species, or create opportunities for new species to invade the area.

	<i>Astronomical</i>	<i>Physical</i>			<i>Biological</i>	<i>Ecogeographical</i>
		<i>Athmosphere</i>	<i>Lithosphere</i>	<i>Hydrosphere</i>		
Structural	Types of astros and constellations	Climate Winds Cloud Snows	Rocks Soils Landforms	Types of waters	Plants Animals Fungi Microorganisms	Vegetation and other landscape units
Relational	Several	Several	Several	Several	Several	Several
Dynamic	Solar and lunar cycles, movements of constellations and stars	Climatic events	Soil erosion	Water flows Water tables	Lifecycles, nesting seasons etc.	Ecological succession
Utilitarian	Several	Several	Several	Several	Several	Management units

Figure 5 Matrix of indigenous ecological knowledge.

However, the number of species is commonly relatively small in highly disturbed biotic communities, because few populations are able to re-establish themselves before they are reduced by later disturbances. In contrast, a low rate of disturbance provides few opportunities for pioneer species and might allow competitively dominant species to usurp limiting resources. Therefore, biodiversity is often greater at intermediate levels of disturbances than lower or higher rates.

The creation of landscape mosaics under the indigenous multiuse strategy in areas originally covered by only one natural community represents a human-originated mechanism which theoretically tends to maintain (and even increase) biodiversity. Several authors have already stressed the importance of the models of low intensity mosaic usage of the landscape by indigenous peoples and other small-landowner populations for biodiversity conservation. The same diversified arrangement found in indigenous landscapes tends to be reproduced at a microlevel, with multispecies, multistory crops, or agroforests favored over monocultures.

As a consequence, animal and especially plant genetic resources tend to be maintained in indigenous agricultural fields, aquaculture systems, homegardens and agroforests (see several examples in Toledo and Barrera-Bassols, 2008). Polycultural systems managed by indigenous agriculturalists and agroforesters are relatively well known and the recent specialized literature has plenty of case studies illustrating such designs. Especially notable are the homegardens and agroforestry systems of the tropical and humid regions of the

world, which operate as human-made refuge areas for many species of plants and animals, notably in areas strongly affected by deforestation (Moguel and Toledo, 1999; McNeely and Schroth, 2006). At farm level, it is broadly recognized that crop populations are more diverse in indigenous farming systems than in agricultural areas dominated by agroindustriality. Therefore, indigenous peoples are recognized as key agents of on-farm preservation of plant genetic resources threatened by agricultural modernization (genetic erosion). The loss of biodiversity is also experienced in farming systems as indigenous cropping polycultural patterns are replaced by fossil-fueled monocrops. Indigenous agricultural systems and landscapes are then acknowledged as designs that preserve not only landraces of crop species, but also semidomesticated and wild crops relatives and even nondomesticated species.

Conserving Biodiversity by Empowering Indigenous Peoples

During the past three decades, as the loss of landscapes, habitats, species, and genes has become an issue of international concern, the protected areas of the world have increased notably both in size and number. However, as protected areas expanded, it became evident that the North originated model of uninhabited national parks could not be applied worldwide. Today, there are nearly 109,000 nationally protected areas (parks and other reserves) in more than 160 countries, which

represent more than 11.5% of earth's land surface (UNEP-WCMC, 2005; World Database on Protected Areas, 2005). Many of the areas that have been established as protected areas and many of those that are suitable for future addition to the protected area network are the homelands of indigenous peoples. In Latin America alone, more than 80% of protected areas are estimated to have indigenous people living within them. However, large tracts of the territories under indigenous control, estimated at between 12% and 20% of the earth's surface, are in the scope of conservationists as future reserves. Moreover, some authors like Nietschmann and Alcorn think that the bulk of the world's biodiversity is embodied within the limits of the indigenous territories of the tropical countries. Given the above, as well as the evidences offered and discussed in the previous sections, the idea that biodiversity conservation is impossible without the participation of indigenous communities is increasingly gaining recognition in national and international conservation circles.

Protected areas based on consultation, co-management, and even indigenous management, are likely to be increasingly important in coming years as the key role of indigenous cultures is being gradually recognized. It is important, however, not to over-idealize indigenous peoples and their resource-management strategies and stewardship skills. Conservationists have been frequently criticized for over-romanticizing indigenous peoples, creating a late-twentieth-century version of "the noble savage." Acknowledgment of the positive links between indigenous peoples and biodiversity has been increasingly tempered by the recognition that under certain circumstances (high population densities, market pressures, unsuitable technologies, local disorganization) indigenous peoples can act as disruptive, not as conservationist, actors.

Biological diversity and sustainable development are today two of the most powerful and central concepts in environmental protection. In recent years, special attention has been paid to the sustainable development of community-based peoples, as a key mechanism for the reinforcement of correct participation of local communities in biodiversity conservation. It is possible to define sustainable community development as an endogenous mechanism that allows a local society to take (or retake) control of the processes that affect it. In other words, self-determination and local empowerment, conceived as a "taking of control," have to be the central objectives in all community development.

Given the demonstrated importance of indigenous peoples for biodiversity conservation, it is essential to recognize the necessity of empowering local communities. That is, to maintain, reinforce, or give control to the indigenous communities of their own territories and natural resources as well as providing sufficient access to information and technology. Important here are legally recognized and enforceable rights to lands and waters, which give the communities both an economic incentive and a legal basis for stewardship. In many countries, national recognition and policy support for existing, community-based property rights systems are crucial. In many Asian and African countries, returning a measure of control over public lands and resources to local communities is also fundamental to slowing biodiversity loss in threatened regions.

Similarly, it is very important to establish new resource-management partnerships between local communities and the

state and other society institutions to maintain biodiversity. Local stewardship in conjunction with external governmental and nongovernmental agencies and institutions is perhaps the best way to guarantee effective protection of landscapes, habitats, species, and genes worldwide, and especially in tropical countries.

Concluding Remarks: A Bio-Cultural Axiom

The research accumulated in the last three decades by investigators belonging to the fields of conservation biology, linguistics and anthropology of contemporary cultures, ethnobiology, and ethnoecology, have evolved convergently toward a shared principle: that the world's biodiversity will be effectively preserved only by preserving diversity of cultures and vice versa. This common statement, which represents a new bio-cultural axiom, has been nourished by four main sets of evidence: geographical overlap between biological richness and linguistic diversity and between indigenous territories and biologically high-value regions (actual and projected protected areas), recognized importance of indigenous peoples as main managers and dwellers of well-preserved habitats, and certification of a conservationist-oriented behavior among indigenous peoples derived from its premodern belief-knowledge-practices complex.

This bio-cultural axiom, called by Nietschmann the "concept of symbiotic conservation," in which "biological and cultural diversity are mutually dependent and geographically coterminous," constitutes a key principle for conservation theory and applications, and epistemologically is an expression of the new, integrative, and interdisciplinary research gaining recognition in contemporary science.

Natural Reserves and Preserves

Alexander N Glazer, University of California, Berkeley, CA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Abyssal Applied to the deepest part of the ocean, below about 2000 m.

Benthos (adj. benthic) In freshwater and marine ecosystems, the collection of organisms attached to or resting on the bottom sediments.

Endemism The situation in which a species or other taxonomic group is restricted to a particular geographic region.

Eukaryote An organism whose cells have a distinct nucleus enveloped by a double membrane and other distinctive morphological features.

Hectare A metric measure of surface equal to 10,000 square meters or 2.471 acres (US).

Hypoxia Decreased partial pressure of oxygen.

Nautical mile The unit of length that is used in ocean navigation, equivalent to one minute (1/60°) change in latitude, internationally defined as equal to 1852 m.

Photic zone The layer of water within which organisms are exposed to sunlight.

Prokaryote An organism, in which the cells lack a true nucleus.

Outline

Protected natural areas cover ~12.5% of the Earth's land surface and ~1.2% of the oceans. Collectively, these areas are critical to slowing the loss of biological diversity. Natural biological communities, undisturbed by humans, are also irreplaceable objects for the scientific study of ecological processes. There are many different types of protected areas: national parks, refuges, and sanctuaries, both terrestrial and marine. In recognition of the fact that the purposes for which particular protected areas are managed vary widely, the International Union for Conservation of Nature has classified protected areas into six categories. Examples are given of protected areas that fall into each of these categories. In addition, more detailed descriptions are given for several terrestrial and marine reserves from different biogeographic realms of the Earth to provide a glimpse of their geological diversity and unique biota. It is increasingly recognized that ecosystems, biodiversity, and natural resources are central to sustaining the global economy, societies, and individual wellbeing. Protected natural areas are a key component of assuring the long-term wise management of the Earth. Unfortunately, there are many direct and indirect threats to the future of these areas.

Origins of Protected Areas

"To qualify as conservation, any action or practice must not only prevent or mitigate resource overharvesting or environmental damage, it must also be designed to do so" (Smith and Wishnie, 2000). Preserves, such as sacred groves, established in ancient times, appear to qualify under that definition, because they do protect those areas in their natural state. Royal hunting parks clearly would not.

Preservation of natural biological habitats for their own value originated relatively recently (Adams and Hutton, 2007). The world's first national park, Yellowstone, was established in 1872. It occupies nearly 9000 km² mainly in the northwestern

corner of Wyoming, and extends into Idaho and Montana. The Yellowstone Act of 1872 reflected the prevailing faith in the inexhaustibility of natural resources. The act prohibited the wanton destruction of fish and game for profit, but it permitted hunting, trapping, and fishing for recreation or to provide food for park residents or visitors. Several other nations established national parks soon after: Australia (Royal National Park, 1879), Canada (Banff National Park, 1885), and New Zealand (Tongariro National Park, 1894). In Africa, and to a lesser extent in the Indian subcontinent, steps toward conservation during the colonial era emphasized large mammals, particularly those that had been intensively hunted. The oldest national park in India, Jim Corbett National Park, a haven for tigers in the Himalayan foothills of Uttar Pradesh, was established in 1936. In contrast, in long-settled parts of Europe, protection was extended to humanized landscapes. Protection has also been given to mangroves and coral reefs. Mangroves are found in the tropics and sub tropics on riverbanks and along coastlines. Mangrove plants include trees, shrubs, ferns, and palms, which have adapted to the largely anaerobic conditions of muddy, aquatic environments by producing stilt roots which project above the water to absorb oxygen. Approximately 900 protected areas include mangroves. Coral reefs, many formed over periods of thousands of years, cover between 300,000 and 600,000 km² mainly between the Tropics of Cancer and Capricorn. The Great Barrier Reef Marine Park off the coast of Queensland, Australia, covers 348,000 km² of reefs and surrounding waters.

The diverse national parks, reserves, and preserves throughout the world, are now referred to as "protected areas." There are over 100,000 protected areas in the world, representing a total area of 18,764,000 km², or over 12% of the world's land surface area. By contrast, as of 2010 only 1.2% of the world's oceans are included in the world's ~5000 Marine Protected Areas. National parks, of which there are currently ~6500 in the world, are among the most popular tourist destinations. In 2009, more than 285 million people visited the national parks in the United States alone.

Table 1 Definitions of the International Union for the Conservation of Nature (IUCN) protected area management categories

Category	Description
I	Ia. Strict Nature Reserve: managed mainly for science Area of land or sea possessing some outstanding or representative ecosystems, geological or physiological features and species, available primarily for scientific research and environmental monitoring. Ib. Wilderness Area: managed mainly for wilderness Large area of unmodified or slightly modified land, or sea, retaining its natural character and influence, without permanent or significant habitation, which is protected and managed so as to preserve its natural condition.
II	National Park: managed mainly for ecosystem protection and recreation Natural area of land or sea, designated to (1) protect ecological integrity of one or more ecosystems for present and future generations, (2) exclude exploitation or occupation inimical to the purposes of designation of the area and (3) provide a foundation for spiritual, scientific, educational, recreational and visitor opportunities, all of which must be environmentally and culturally compatible.
III	Natural Monument: managed mainly for conservation of specific natural features Area containing one, or more, specific natural/cultural feature which is of outstanding or unique value because of its inherent rarity, representative or esthetic qualities or cultural significance.
IV	Habitat/Species Management Area: managed mainly for conservation through management intervention Area of land or sea subject to active intervention for management purposes so as to ensure the maintenance of habitats and to meet the requirements of specific species
V	Protected Landscape/Seascape: managed mainly for conservation and recreation Area of land, with coast and sea as appropriate, where the interaction of people and nature over time has produced an area of distinct character with significant esthetic, ecological, or cultural value, and often with high biological diversity. Safeguarding the integrity of this traditional interaction is vital to the protection, maintenance, and evolution of such an area.
VI	Managed Resource Protected Area: managed mainly for the sustainable use of natural ecosystems Area containing predominantly unmodified natural systems, managed to endure long-term protection and maintenance of biological diversity, while providing at the same time a sustainable flow of natural products and services to meet community needs.

Table 2 Global number and extent of protected areas for 2003 for sites with assigned IUCN Category (excluding noncategorized sites)^a

Category	Number of sites	% of categorized sites	Area covered (km ²)	Proportion of total area protected (%)
Ia	4731	7.0	1,033,888	6.8
Ib	1302	1.9	1,015,512	6.7
II	3881	5.7	4,413,142	29.0
III	19,833	29.1	275,432	1.8
IV	27,641	40.6	3,022,515	19.9
V	6555	9.6	1,056,008	7.0
VI	4123	6.1	4,377,091	28.8

^aTotal number of protected sites in 2003 was 102,102. Of these, 34,036 were noncategorized sites. The noncategorized sites covered an area of 3,569,820 km². The total area covered by all 102,102 sites was 18,763,407 km².

Source: Reproduced from Tables 1 and 2 of Chape S, Blyth S, Fish L, Fox P, and Spalding M (2003) *2003 United Nations List of Protected Areas*. Gland, Switzerland and Cambridge, UK: IUCN/UNEP-WCMC.

Classification

The International Union for the Conservation of Nature (IUCN) defines a protected area as “a clearly defined geographical space, recognized, dedicated, and managed, through legal or other effective means, to achieve the long-term conservation of nature with associated ecosystem services and cultural values” (Dudley, 2008). IUCN noted that the purposes for which particular protected areas are managed vary widely and noted specifically (1) scientific research, (2) wilderness protection, (3) preservation of species and genetic diversity, (4) maintenance of environmental services, (5) protection of specific natural and cultural features, (6) tourism and recreation, (7) education, (8) sustainable use of resources from natural ecosystems, and (9) maintenance of cultural and traditional attributes. IUCN classified protected areas into the

six categories listed in Table 1, reflecting the management purpose. Note that IUCN categories IV–VI encompass areas where limited or extensive use of biological resources is allowed. The following discussion of the characteristics of representative protected areas belonging to each of the categories in Table 1 clarifies the distinctions. Table 2, based on 2003 data, shows the global number of sites within each IUCN category.

Extent of Protected Areas of the World's Major Terrestrial Biomes

The terrestrial extent of protected areas is ~12.5% of the land surface, an area almost equal to that of the entire continent of South America. Summary statistics published in 2003,

Table 3 Extent of protection of the world's major terrestrial biomes

Biome name ^a	Area (km ²)	Total number of sites	Extent (km ²)	% Biome protected
Tropical humid forests	10,513,210	3422	2,450,344	23.31
Subtropical/temperate rainforests/woodlands	3,930,979	6196	665,174	16.92
Temperate needle-leaf forests/woodlands	15,682,817	13,297	1,350,221	8.61

^aBiogeographical classification based on Udvardy MDF (1975) *A Classification of the Biogeographical Provinces of the World* (Occasional Paper no. 18). Gland, Switzerland: International Union for the Conservation of Nature and Natural Resources.

Source: Based on data in Table 4 in Chape S, Blyth S, Fish L, Fox P, and Spalding M (compilers) (2003) *2003 United Nations List of Protected Areas*. Gland, Switzerland and Cambridge, UK: IUCN/UNEP-WCMC.

presented in **Table 3**, are based on a framework that classifies the world into eight biogeographic realms, 203 biogeographic provinces, and 14 biomes (Udvardy, 1975). Protection of temperate grasslands and of lake systems is much lower than that of the other biomes. Recently published results of a draft analysis, based on new, global-level land-cover maps, are in reasonable agreement with those provided in **Table 3**, but show somewhat higher levels of protection for some biomes (see Table 3 in UNEP-WCMC, 2009).

Representative Terrestrial Protected Areas

The protected areas described below exemplify each of the IUCN categories I–VI (see **Table 1**).

Snares Islands/Tini Heke Islands

The subantarctic Snares Islands/Tini Heke Islands, located 209 km southwest of Bluff on South Island of New Zealand, belong to the most diverse and extensive of all subantarctic archipelagos. The islands are made of granite and metamorphic rocks more than 100 million years old. They are classified as category Ia (Strict Nature Reserve) because the vegetation is nearly pristine and the islands are free of introduced mammals. The total area of the Snares Islands Nature Reserve is 328 hectares, covering the islands and their foreshores. The islands are home to millions of breeding seabirds, including the endemic Snares crested penguin, and are strictly protected. Research and monitoring of natural plant and animal communities that does not cause long-term disturbance or damage is permitted. There is no access for tourists.

North East Svalbard Nature Reserve

North East Svalbard Nature Reserve, owned by the Norwegian government, exemplifies category 1b (Wilderness Area). The

reserve includes the islands of Spitzbergen, Nordaustlandet, Edgeø, Barentsø, and Prins Karls Forland, and the surrounding territorial waters, a total of 1.9 million hectares, in the northeast of the Svalbard archipelago. The archipelago extends approximately from 74° to 81° N and from 10° to 35° E, an Arctic area about one and a half times the size of Switzerland. This wilderness is covered by high arctic tundra vegetation, with many species near their northernmost distribution in Europe. The large mammals include polar bear, reindeer, and walrus. Access is limited to nonintrusive scientific research and recreation.

Canaima National Park

Canaima National Park (category II, National Park), owned by the Venezuelan government, covers 3 million hectares centered on the Guayana Shield in Bolivar State, south of the Orinoco River. Canaima includes the uplands of the Grand Sabana and the eastern tepuis of the Roraima Range. The tepuis are flat-topped mountains with almost vertical slopes. The world's highest waterfall, Angel Falls, with a fall of 102 m, descends from one of these mountains. The summits of the tepuis have rich flora and fauna with high endemism and form a unique archipelago of isolated but related ecosystems. A small population of traditional occupants of the area, the Pémon, continues swidden (slash-and-burn) agriculture, hunting, and gathering. The park preserves representatives of the geological, biological, and cultural features specific to the Guayana Shield. Hunting and collecting of wildlife is forbidden. Recreational activities, research, and education are encouraged.

Jenolan Karst Conservation Reserve

Jenolan Karst Conservation Reserve (category III, Natural Monument) covers an area of 2694 hectares on the eastern margin of the Oberon Highland Plateau (33°49'14" S, 150°1'17.2" E) in New South Wales, Australia. Much of the

area was put aside in 1866 to “protect a source of delight and instruction to succeeding generations and excite admiration of tourists from all parts of the world.” This was one of the earliest implementations of conservation for the protection of noncommodity values. The reserve offers outstanding examples of karst landforms and natural phenomena. “Karst” refers to the processes, landforms, and landscapes displaying solutional weathering along surface and subsurface pathways. Karst is usually associated with porous rocks of high solubility, such as limestone or gypsum. An estimated 7–10% of the Earth’s ice-free land surface comprises karst terrain. The Jenolan Karst Conservation Reserve terrain was formed by selective dissolution of limestone by acidic natural waters, leading to the formation of a karst landscape of sinkholes, a network of connected cave passages and speleotherms. At over 340 million years old, this cave complex is the world’s oldest known and dated open cave system (Osborne, 2010). In addition to its geologic features, the reserve protects rare and endangered flora species and faunal communities totaling over 360 species, including 147 species of troglolithic fauna. Over 250,000 people visit this reserve annually.

Selous Game Reserve

Selous Game Reserve (category IV, Habitat/Species Management Area) is situated in southern Tanzania (7°20′–10°30′ S, 36°00′–38°40′ E). At 5 million hectares, it is one of the largest protected areas in Africa, with altitudes ranging from 100 to 1200 m. Prior to the 1930s numerous villages were in the area currently within the reserve. Periodically, sleeping sickness epidemics would sweep through the area. Control of marauding elephants, which consistently consumed a quarter to a third of the food crop production, was a constant problem. During the period of British colonial rule in Tanzania, between 1919–1961, the authorities would order evacuation of areas affected by sleeping sickness and permanent relocation of the inhabitants. Between 1933 and 1942, some 30,000 inhabitants of an area currently within the Selous Game Reserve either moved voluntarily or were relocated, and the elephants then largely driven into the expanded reserve area (Neumann, 2001). Prior to 1930, the land currently within the Selous reserve included a mosaic of human occupation, much like Dartmoor area today (see below). The current, seemingly pristine wilderness is a relatively recent product of the actions described above. The Selous Game Reserve protects the world’s largest area of the deciduous miombo woodland, where the trees grow to heights of 15–20 m, rising over a broadleaf shrub understory with grassland underneath. This woodland requires a particular burning regime for its preservation. The Reserve has a higher density and species diversity than any other miombo woodland area. Selous is famous for its elephant, hippopotamus, and black rhinoceros populations, although only 100–400 of the rhinoceros remain. Sizable populations of other large animals include buffalo, Nyasaland gnu, brindled gnu, hartebeest, Greater Kudu, sable antelope, eland, reedbuck, bushbuck, waterbuck, warthog, zebra, giraffe, and wildebeest. Predators include lion, leopard, spotted hyena, hunting dog, and a small population of cheetah. There are more than 350 species of birds and reptiles, including

crocodiles. Ecological monitoring and research provide information for the quotas for regulated sport hunting, the main use of the reserve.

Dartmoor National Park

Dartmoor National Park (category V; Protected Landscape/Seascape) was designated one of the national parks of England and Wales in 1951. It was accepted in Britain that beautiful areas of open space, encompassing mosaics of farms, villages, and small towns, were worthy of protection. National park designations were given to such areas, without requirement that they be pristine. Management of the Park aims to ensure preservation of the natural habitat, the cultural heritage of the area, and continuation of traditional agricultural uses. Dartmoor National Park is a moorland landscape with tors of exposed granite and wooded valleys. It is a rich habitat for wildlife and includes lowland farming areas of meadow, pasture, and woodland, deep valleys, and upland moors. There is a wealth of archeological remains. Approximately 31,000 people live within the 91,300-hectare area of the park. About 10 million visitors come to the Park for recreation each year. Management of the area aims to ensure preservation of the natural habitat, the cultural heritage of the area, and continuation of traditional agricultural uses.

Tamshiyacu-Tahuayo Communal Reserve

Tamshiyacu-Tahuayo Communal Reserve (category VI, Managed Resource Protected Area), established in 1991, is an area of 332,500 hectares of Amazonian rain forest in the state of Loreto in northeast Peru and encompasses a rich flora and fauna. The reserve is divided into three land zones: a totally protected core, a subsistence zone, and an area of permanent settlement. More than 6000 people exploit the resources of the subsistence zone and the bordering areas. These people, broadly characterized as *ribereno* peasants, depend on small-scale agriculture, hunting, fishing, and gathering of nontimber plant products. Peruvian Communal Reserves are a category of protected areas “which secures exclusive use of rights over large, natural areas for the benefit of neighboring rural populations” (Newing, 2009, p. 98). In the long-term, an issue with this approach is that rural communities do not retain a clearly defined membership, because they change in composition and size, cultural characteristics, and consensus. These changes were evident in the makeup of communities on the boundary of Tamshiyacu-Tahuayo Communal Reserve within 20 years of its establishment (Newing, 2009).

Extent of Marine Protected Areas

In comparison to terrestrial biodiversity, marine biodiversity receives much less protection. Biodiversity in the ocean is in decline with huge losses of big fish species, widespread damage to coral reefs, and multiple “dead zones” with low oxygen levels lethal to many marine organisms.

The formal designation of marine protected areas was initiated in the 1970s and the number has grown rapidly in

Table 4 Marine protected areas by IUCN category

recent years. A tabulation of marine protected areas by IUCN category (Table 4 in Mulongoy and Chape, 2004) showed that they covered ~0.42% of the global ocean area, whereas protected areas cover ~12% of the earth's terrestrial surface. A 2010 estimate indicates that the coverage by marine protected areas has increased to ~1.2%. Much of the protected area is attributable to two very large sites. The Great Barrier Reef Marine Park and the Northwest Hawaiian Islands Coral Reef Ecosystem Reserve together represent over 680,000 km².

There are no marine protected areas entirely within international waters. About 63% of the world's ocean area lies beyond 200 nautical miles (nm) of any coastline and consequently beyond claims of national jurisdiction. A few of the largest marine protected areas extend into the 200 nm zone, the others lie within the 3–12 nm territorial waters of a nation's coastline (Mulongoy and Chape, 2009).

Most protected marine areas are in coastal and continental shelf waters, where they protect the intertidal and subtidal terrain and biota. These areas are also contributing significantly to increase in fish stocks in the protected area and beyond, through the migration of larvae and fish out of the protected area.

Examples of Marine Protected Areas

The four protected areas described below provide a glimpse of the amazing wealth of biodiversity within marine reserves.

Great Barrier Reef Marine Park

Great Barrier Reef Marine Park is a maze of about 2900 individual reefs covering 345,400 km² on the northeast continental shelf of Australia and includes 600 continental islands. The Park's northern boundary is from 10°41' S running east up to the eastern edge of the Great Barrier Reef at 145°19'33" E. The current Great Barrier Reef structure started growing on top of an old reef platform about 9000 years ago when the sea levels gradually rose at the end of the last Ice Age about 20,000 years ago. It is the world's largest reef system. The Park's relatively pristine area has been poetically described as "the largest living organism in the world." More accurately, the Great Barrier Reef encompasses a tight web of interactions among thousands of different living organisms within a very special environment. The area is a treasure trove of

biodiversity with over 360 species of hard, reef-building corals, 4000 mollusk species, and over 1500 species of fish. The islands and keys support over 200 bird species, and over 2000 plant species. There are extensive seagrass beds. The reef provides habitat for endangered species, such as the dugong and the loggerhead turtle, and a breeding area for the humpback whale.

Papahānaumokuākea Marine National Monument

Papahānaumokuākea Marine National Monument (Northwestern Hawaiian Islands Marine National Monument) consists of small islands, atolls, submerged banks, and reefs that extend for more than 2000 km northwest of the main Hawaiian Islands. Partial protection of much of the area now within the Monument dates back to 1909, when as a response to the overharvesting of seabirds, and in recognition of the islands' importance as seabird nesting grounds, President Theodore Roosevelt through an Executive Order created the Hawaiian Island Reservation. The current ~362,000 km² Monument was created in 2006 by a Presidential Proclamation by President George Bush. The majority of the islets and shoals are currently uninhabited.

Like the main Hawaiian Islands, the Monument is notable for having flora and fauna with some of the highest marine endemism in the world. Remote and protected, the Monument supports significantly more fish biomass than the heavily fished Main Hawaiian Islands. Large apex predators, reef sharks and jacks, account for over half of the fish biomass. The Monument is home to one of the largest and most important assemblages of seabirds in the world, and also provides important habitat for a number of threatened and endangered species, such as the Hawaiian monk seal, one of the most critically endangered marine mammals in the USA with a reported population in 2005 of 1400, and for over 90% of all Hawaiian green sea turtles. The shallow waters of the Monument have 57 stony coral species, of which 17 endemic species account for 37–53% of the relative abundance of stony corals on each reef within the monument. There are 350 different algal species. The remoteness, limited human presence, protected status and near-pristine condition of the North Hawaiian Islands allow detailed studies of the structure and functioning of coral reef ecosystems. The Monument protects a baseline site for the detection and assessment of human impacts on such systems.

Bowie Seamount Marine Protected Area (Sgaan Kinghlas)

A huge column of upwelling lava, known as a "plume," lies at a fixed location under the Pacific Plate, located beneath the present-day position of the Island of Hawaii. As the ocean floor moves over this "hot spot" at about 12 cm a year, the upwelling lava creates a succession of new volcanoes that migrate along with the plate. Bowie Seamount Marine Protected Area (Sgaan Kinghlas), a part of the Kodiak-Bowie seamount chain, is located at 53°17'58.9" N/135°39'02.5" W. It encompasses the Bowie, Hodgkins, and Davidson seamounts, and covers ~6130 km². This discontinuous chain of extinct volcanoes reflects the movement of the Pacific plate

over the Bowie hotspot. Bowie, formed 0.075–0.7 Mya, is the youngest volcano in this chain. Bowie is an enormous seamount with a base depth of 2800 m and a peak depth of 34 m. Seamounts are usually extinct volcanoes that have been covered by the sea, and Bowie was once a volcanic island (during the last Ice Age). It is estimated that there may be as many as 200,000 seamounts of 100 m or higher in the oceans. Fewer than 300 seamounts have been thoroughly studied.

Because of their physical characteristics seamounts can generate upwelling of nutrients and currents that trap small migrating organisms. The resulting enhanced primary production attracts birds, mammals, and large pelagic fish, and fisheries. Compared to the surrounding deep-sea, the benthic community is generally more diverse and abundant than that in the surrounding deep-sea. Seamounts can have comparable levels of benthic diversity and endemism to continental margins. The Bowie area was selected for special protection because of high primary productivity. A productive algal community is associated with part of the seamount that lies within the photic zone. The diverse oceanic, coastal, and seamount species include several species at risk, including the killer whale (*Orcinus orca*), the Steller sea lion (*Eumetopias jubatus*), and ancient murrelet (*Synthliboramphus antiquus*).

The Endeavor Hydrothermal Vents Marine Protected Area

Abyssal plains, underwater plains on the deep ocean floor, cover more than half of the Earth's surface. Abyssal food chains are fueled by organic debris that sediments down to the ocean floor. This limited food source supports a sparse population of abyssal fauna. A very different situation is seen in active seafloor-spreading zones where tectonic plates separate and new oceanic crust is extruded onto the seafloor. Here, cold seawater percolates down through the crust, and comes into contact with the underlying molten lava. The particle rich, superheated fluid emerges through the seafloor as buoyant flumes. Such hydrothermal vent fields support faunal biomass productivity, sometimes a thousand-fold higher than that of the surrounding deep sea, and comparable to that of the most productive marine ecosystems. More than 100 vent fields have been documented along the 60,000-km global mid-ocean ridge system.

In 2003, Canada established the first marine protected area for the conservation of deep ocean hydrothermal vents. The 82 km² Endeavour Hydrothermal Vents Marine Protected Area (47° N/129° W), 250 km southwest of Vancouver Island, at a depth of 2250 m, is within the Endeavour Segment of the Juan de Fuca ridge system, and encompasses five vent fields. These fields span hydrothermal venting conditions varying in water temperature, salt content, and mineral chimney morphology. The mineral composition at Endeavour vent sites has been extensively analyzed. Black smokers, with vigorous hydrothermal flow and exit temperatures typically in the range of 250–350 °C, emit black “smoke.” The emissions are rich in Fe, S, Ca, Cu, and Zn. The “smoke” consists of particulate and dissolved metal-rich sulfide (anhydrite, chalcopyrite, sphalerite, barite) and sulfate minerals, products of high-temperature mixing between vent fluids and oxygen-containing cooler seawater. The volcanic emissions from black smokers have

substantial amounts of dissolved CO₂, H₂S, H₂, and small amounts of methane. These dissolved gases and metals sustain microbial communities that, in turn, serve as the base of the food chain for communities of prokaryotes and eukaryotes of five hundred or more different species of organisms, characteristic of these very special sites. The discovery in 1977 of vent fauna, with its unique suite of organisms and extraordinary metabolic pathways, amazed the scientific community, and gave rise to the speculation that life may have originated in such hydrothermal vent environments.

Threats to Marine Protected Areas

Marine protected areas are vulnerable to the severe, pervasive, and increasing threats to biodiversity in the oceans: the major threats include overfishing, bottom trawling, ocean acidification, and “dead zones,” where the water, particularly at the sea floor, is anoxic meaning that the dissolved oxygen concentration is very low or zero.

Persistent oxygen minimum zones, exhibiting severe hypoxia (<0.5 ml O₂ l⁻¹), occur naturally in coastal upwelling zones rich in nutrients at intermediate depths of 200–1000 m, sometimes extending to the ocean floor. In those areas the benthic fauna is adapted to dissolved oxygen levels as low as 0.1 ml O₂ l⁻¹. Such zones occur primarily in the eastern Pacific, in the Atlantic west of Africa, the Arabian Sea, and the Bay of Bengal. Since the 1960s, severe hypoxia gradually developed in many coastal areas with nutrient-rich runoff from population centers and watersheds, giving rise to “dead zones,” with mass mortality in the benthic community. There is abundant evidence that the dead zones are produced in response to the delivery of large quantities of nitrogen fertilizers, organic waste and so on. For example, the size of the dead zone in the northern Gulf of Mexico is tightly coupled to the nutrient-rich discharge from the Mississippi River. During years with low river flow, the area of hypoxia is <5000 km², and increases to >15,000 km² when the river flow is high. Dead zones have now been reported from over 400 widespread locations and affect a total area of more than 245,000 km² (Diaz and Rosenberg, 2008).

Deep-sea areas (below 200 m) cover over 60% of the surface of the Earth. A large fraction of this yet-to-be-adequately-explored area lies beyond the zone of exclusive control of individual nations and is open to fishing and a variety of highly ecosystem-damaging practices. Distinctive deep-sea habitats include seamounts, hydrothermal vents, cold seeps, and cold-water corals. The abyssal muds that cover some 75% of the ocean floor below 3000 m, more than half the surface of the Earth, have a rich biota supported by bacterial degradation of the organic matter that settles on the deep-sea floor. The bacteria, adapted to these great depths were first cultured in 1952, and can only be cultivated under a hydrostatic pressure of ~1000 atmospheres and low temperature. In the deep ocean, these bacteria serve as rungs in a food chain, as food for protozoans or filter-feeders. Bottom trawling destroys large swaths of the abyssal habitat.

As noted above, seamounts attract intensive commercial fisheries, whose trawling activities cause severe ecological damage to seamount biota. Other threats, present and

anticipated, include mining manganese nodules, cobalt-rich ferromanganese crusts, polymetallic sulfide deposits, and precious metals at sites of hydrothermal activity, as well as oil and gas extraction with attendant chemical pollution.

Ocean acidification presents a looming enormous threat to ocean biodiversity (Secretariat of the Convention on Biological Diversity, 2009). The oceans take up nearly half of the carbon dioxide (CO₂) produced by the burning of fossil fuels. As shown below, CO₂ reacts with water to form carbonic acid. As shown in the equation below, the protons produced by the dissociation of the carbonic acid acidify the ocean and the carbonate concentration drops as the equilibrium between carbonate and bicarbonate shifts toward bicarbonate.

To date the decrease in the ocean pH is 0.1, but is projected to fall another 0.3–0.4 units by the year 2100, assuming that combustion of fossil fuels will continue at the present rate. Such acidification will affect the process of calcification, by which corals and molluscs make shells and plates from calcium carbonate. The tropical and subtropical corals would be among the worst affected, with negative implications for the stability and longevity of the reefs that they build and the organisms that depend on them. Cold-water coral reefs are also likely to be adversely affected (Royal Society, 2005). An acidification event of the projected magnitude that occurred 55 million years ago was accompanied by the extinction of a large proportion of benthic calcifiers.

Values of Natural Reserves and Preserves

Over the past 50 years, the number of natural reserves and preserves around the world has grown to over 100,000 by 2003, and concomitantly the protected area increased exponentially to nearly 13% of the land surface and ~1.2% of the oceans. From the outset, preservation of biodiversity has been the dominant objective. About 1.75 million species of plants, animals, insects, and microorganisms have been identified. Estimates of the actual number of species range from 3 to 13 million. The fraction of the total biodiversity on Earth protected within natural reserves and preserves is not known, but many of the ecosystems that occur in the deserts, forests, wetlands, mountains, lakes, rivers, and oceans, are represented in the protected areas.

The irreplaceable values of natural reserves and preserves include wilderness protection, preservation of species and genetic diversity, and scientific research. Other objectives addressed by protected areas are maintenance of environmental services, sustainable use of resources from natural ecosystems, protection of specific natural and cultural features, maintenance of cultural and traditional attributes, education, tourism, and recreation.

Funding of the Management of Protected Areas

Funding of the protection and management of many natural areas is grossly inadequate. As a result, numerous designated

natural reserves are *de facto* paper parks. Arguments for enhanced support have in recent years stressed that the economic benefits provided by natural areas far exceed the required investment. Such arguments are bolstered by examples of ways in which protected areas slow down global climate change, such as the following.

- The 39 Canadian national parks sequester 4 billion tons of carbon dioxide estimated to be worth US\$39–87 billion in carbon credits.
- In the Brazilian Amazon, protected lands, including state parks and indigenous reserves, are estimated to prevent the deforestation of 670,000 km² by 2050, thereby avoiding the release of 8 billion tons of carbon dioxide into the atmosphere.

However, such impressive benefits do not guarantee that even modest necessary funding will materialize. For example, a 2010 report on the financial sustainability of protected areas in 20 Latin American and Caribbean countries with a combined population of 584 million, documented that the available funds of \$314 million per year only addressed basic management activities, whereas more adequate management would require an additional \$700 million per year. This funding gap is of particular concern because this region has 4111 designated protected areas covering a surface of around 500 million km², of which 466 million are terrestrial and 34 million are marine, and contains almost 40% of the Earth's biodiversity (Bovarnick *et al.*, 2010).

Threats to the Future of Protected Natural Areas

From a biological perspective, the majority of individual terrestrial natural reserves and preserves are isolated islands in a sea of exploited lands. Nominally sanctuaries for wildlife and forests, they are subject to hunting, fishing, the wildlife trade, logging, fuel wood and fodder collection, mining, oil and gas extraction. Depending on the particular area, these activities may be legal, or, more frequently, illegal. Activities, such as poaching for the commercial bushmeat trade, may be pursued by park dwellers, or by outsiders, in extreme cases leading to the disappearance of the species for which the protected area was created. Illegal logging, frequently focused on a few valuable species, threatens forests in many protected areas. Accidentally or deliberately introduced alien invasive species, or illegally cultivated commercial plants, are also widespread threats.

Sustaining Biodiversity in a Rapidly Changing World

The design of protected areas is key to ensuring their long-term value. Even if they are secure from threats such as those described above, they also need to be of the right size and shape and contain all the habitats needed to sustain their biota. If the protected area is isolated and the surrounding natural habitat substantially altered, the populations of many of the species within the protected area may in the long-term be too small to survive. A study of an 86-hectare woodland,

the Bogor Botanical Gardens in west Java, offers a classic example. The woodland became isolated when the surrounding forest was destroyed in the mid-1940s. Out of the 62 bird species breeding in the Gardens during 1932–1952, 20 had disappeared by 1980–1985, four were close to extinction, and populations of five more had declined. Although the wooded habitat within the Gardens was protected, it was too small to retain self-sustaining populations of many woodland bird species without the pre-1940s surrounding habitat (Diamond *et al.*, 1987).

The example of the Bogor Botanical Gardens illustrates the vulnerability of small reserves to changes in the use of the surrounding lands. Is this also a concern for very large protected areas?

The world's first national park, Yellowstone National Park covers 8987 km² of which 80% is forest. By 2007, ~37% of the surrounding lands had been converted to intensive human uses including grazing. Since its establishment in 1872, the Park has managed to preserve its wildlife population. The American bison was saved from near extinction through the protection extended in the Park in 1902 to the then remnant population, which reached a low of ~25. The population now fluctuates between 2200 and 4900 depending on season, winter weather, and management. Since at least 1917, the Yellowstone bison have been infected with the bacterium *Brucella abortus*, possibly through contact with cows that were grazed within the Park at that time. Montana and Idaho, the states adjoining the Park, now have brucellosis-free status that provides significant economic benefits to a state's cattle industry. Local livestock officials are concerned that bison could transfer brucellosis to domestic livestock, jeopardizing that status. No such cases of brucellosis transmission in an open range setting have been verified scientifically (Kilpatrick *et al.*, 2009). Since the year 2000, to prevent bison that wander out of the Park from coming near grazing cattle, such bison have either been driven back into the Park or culled. More than 3400 bison have been killed since 2000, and the average bison population within Park is capped at its estimated carrying capacity of 3000. Yellowstone National Park has become a cage for the bison. The inflexible boundaries of protected areas do not conform to the natural ranges of the species they aspire to protect and currently can do little to extend the protection beyond these boundaries.

Climate Change – A Global Challenge to the Protection of Biodiversity

The Intergovernmental Panel on Climate Change projects that by 2050 climate change may be the major cause of biodiversity loss. The biodiversity at highest risk is that of Mediterranean-climate ecosystems, deserts, coral reefs, sea-ice, mountains, and boreal forests. In the Amazon, the climate models indicate significant reductions in precipitation that might lead to the transformation of evergreen tropical forests into grasslands.

The case histories presented above show that for many protected areas, large and small, migration of species to neighboring lands may not currently be possible. Climate change will increase the probability and extent of shifts in the distribution of species, habitats, and ecosystems. Confronting

this scenario requires implementation of landscape-level planning to provide secure buffers to expand the high-quality habitats within current protected areas wherever feasible, identifying and securing movement corridors to link protected areas, and, more broadly, improving habitat connectivity in anticipation of species spread in response to the impact of climate change on their current locations. The recently established Great Limpopo Transfrontier Park and the Seamount Marine Management Area show the influence of the above recommendations on the expansion of connectivity and size of existing protected areas.

Great Limpopo Transfrontier Park

The Great Limpopo Transfrontier Park in South Africa is a work in progress. Planning started in 2000, but official opening of the Transfrontier Park is still a few years in the future until full removal of fences allows free movement of animals and people along the length of the international borders within the boundaries of the park. The 35,000 km² Transfrontier Park will link the Limpopo National Park in Mozambique, Kruger National Park in South Africa, Gonarezhou National Park, Majinji Pan Sanctuary and Malipati Safari Area in Zimbabwe, and two areas between Kruger and Gonarezhou – the Sengwe communal land in Zimbabwe and the Makuleke region in South Africa.

There is much yet to be learned about the biodiversity within the full area to be included in Great Limpopo Transfrontier Park, but the Park encompasses a wide range of habitats. The species diversity and endemism in Kruger National Park has been surveyed. *Inter alia*, Kruger National Park is home to 18 mammals species on the IUCN Red List of Threatened Species, notably, the wild dog (*Lycaon pictus*) with a population of ~300 and a similar size population of the black rhino (*Diecros bicornis*). The increased range opportunities in the Mozambique and Zimbabwe areas of the Park will contribute to the conservation of such threatened species.

In South Africa, transfrontier conservation activities are encouraged by the belief that as boundaries are dissolved local benefits grow as conservation and development spread regionally. The intent is to achieve benefits for the local people by increasing employment opportunities in service sector activities, such as nature-based tourism, with resulting decrease in dependence on natural resources, that is by bridging conservation and development through 'community-based natural resources management'. The effectiveness of this approach is controversial (Dressler and Büscher, 2008).

Seamounts Marine Management Area

The 2390-hectare Cocos Island, located 530 km southwest of the coast of Costa Rica, is the only major oceanic island of the eastern tropical Pacific with wet rainforest and, above 500 m, a cloud forest. The island also possesses the most diverse and extensive coral reef in the east Pacific, and serves as a reservoir for the larvae of marine species. The waters surrounding the island are famous for the exceptionally high abundance of sharks, including reef sharks, whale sharks, scalloped hammerhead sharks, and of other large ocean predators.

Scalloped hammerhead sharks are on the globally endangered list. These sharks are targeted by fishermen for their fins, which are in high demand, particularly on the Chinese market. Protection of the remaining leatherhead turtles is also an urgent concern. Leatherhead turtles are listed as Critically Endangered on the IUCN Red List of Threatened Species. The Costa Rican population has declined by 90% in the past 20 years, due in large measure to illegal harvesting of eggs in nesting sites. The turtles are also accidentally caught in commercial fishing operations.

In 1978, the island was designated a National Park (IUCN category II), and in 2002 the limit of the protected zone for the surrounding marine ecosystems was extended to 22.2 km from shore. The Las Gemelas Seamounts, a complex underwater mountain system, 35 miles south of Cocos Island, harboring an ecosystem that includes deep-sea corals, sponges, crabs, sea urchins, starfishes, sea cucumbers, and deep-sea fish, lay outside of this protected zone. No trawling has taken place at Las Gemelas seamounts, so that they have retained a relatively intact habitat.

In 2011, the Costa Rican government created a 9640-km² marine management area around Cocos Island that encompasses Las Gemelas seamounts. Purse seining is excluded in the expanded management area, but unfortunately long-lining will still be allowed in much of this protected area.

Glossary

Acid deposition Precipitation or dry fall-out with a pH of less than 5.0.

Anthropogenic Related to the activities of human beings.

Biodiversity Total inventory of genes, organisms, species, populations, communities, and their habitats.

Biogeochemical cycles Pathways and storage of chemical elements through the biota and geologic resources, including the atmosphere, hydrosphere, and lithosphere.

Biomagnifications The increase in body burden of persistent pollutants in organisms at higher trophic levels in food webs.

Climate change Variability of weather over time.

Ecotoxicology The study of chemical stressors on ecological resources.

Food web The pathways of energy and nutrient movement between organisms in an ecosystem.

Hydrologic cycle The movement of water between the surface of the earth and the atmosphere.

Nitrogen saturation Nitrogen levels in excess of the biological nitrogen needs of an ecosystem potentially causing adverse ecological effects.

Ozone Tri-atomic oxygen naturally present (and beneficial) in the stratosphere but present in the troposphere (due to human activities) in amounts potentially toxic to the biota.

Pollution Materials or chemicals in excess of natural levels caused by the activities of humans.

Introduction

Biodiversity includes the total inventory of genes, organisms, species, populations, communities, and their environments, and it integrates all of their complex interactions. This chapter focuses on the approximately 1.4 million species of living organisms known to presently exist on earth while recognizing that this total may represent fewer than 15% of the actual number (Raven and Wilson, 1992). Over geologic timescales, species numbers have been very dynamic. Massive species disappearances have occurred as follows: dinosaurs and marine reptiles in the Cretaceous (66 million years ago), reptiles and conodonts in the Triassic (210 million years ago), trilobites and marine animals in the Permian (250 million years ago), marine reef plants and animals in the Devonian (365 million years ago), and nautiloids and small ocean animals in the Ordovician (440 million years ago). Their mass extinctions are presumed to have resulted from earth impacts (asteroid collision?), climatic change, or large-scale alteration of biogeochemical cycles.

Changes in major element biogeochemical cycles over geologic time have been responsible for the appearance and disappearance of life forms. Changes in the oxygen cycle, for example, which allowed increased concentrations of oxygen gas in the troposphere and ozone in the stratosphere, allowed the evolution of life on earth to proceed. Major episodes of volcanic activity, resulting in marine eruptions and the release of sulfur containing and particulate pollutants, has periodically destroyed life.

Contemporary losses of species are recognized to result from physical stressors (e.g., habitat loss, harvesting), biological stressors (e.g., exotic organism introductions), and chemical stressors (changes in biogeochemical cycles, pollution). This chapter focuses on the latter group of stressors. Presently

humans are recognized to have the ability to alter global and regional biogeochemical cycles via air, water, and soil pollution. As a result, the impact of pollution on biological diversity is a contemporary concern of major dimension (Barker and Tingey, 1992; Peters and Lovejoy, 1992).

Perturbation of the Carbon Biogeochemical Cycle

Mineral carbon is located in a limestone (CaCO_3) reservoir from which it may be leached into a mineral solution as dissolved hydrogen carbonate (HCO_3^-) formed when dissolved CO_2 reacts with CaCO_3 . In the atmosphere carbon exists as carbon dioxide (CO_2). Carbon dioxide in the atmosphere is transferred to the biosphere via photosynthesis. Organic (fixed) carbon in the biosphere is ultimately returned to the atmosphere as CO_2 via microbial decomposition of organic matter. Another fraction of carbon is ultimately fixed as coal, petroleum, and natural gas. This fraction may return to the atmosphere as CO_2 via combustion.

In recent decades, human activities have accelerated the return of CO_2 to the atmosphere via increased deforestation, biomass burning (Nepstad *et al.*, 1999), and fossil fuel combustion (IPCC, 1996).

The accelerating input of CO_2 to the atmosphere from human deforestation and fossil fuel combustion (very approximately 8 billion metric tons annually) (Figure 1) is a significant driver of global climate change. In addition, the incomplete combustion of fossil fuels generates a variety of toxic and precursor compounds that contaminate the atmosphere and ultimately may cause adverse effects on plant and animal populations. Both of these stressors (i.e., climate change and air pollutants) have significant potential to reduce biological diversity.

Figure 1 The global carbon cycle. The storage (numbers without arrows) and the annual flows (numbers with arrows) are shown for the global system. The units are petagrams of carbon ($= 10^{15}$ g C = one gigation = 1 billion metric tons).

Climate Change

Climate is defined as the time averaged value of meteorological quantities. Over time, climate, like an ecosystem, is characterized by change not constancy. In geological terms, the climate of the earth is most typically characterized by extended "moderate periods" with equable weather the year round, lack of ice caps, and generally warm seas. Humans evolved after the last "moderate period" and our development has been in a period of climatic revolution. This period of revolutionary climatic alteration has been characterized by a complex of "cycles within cycles." Over the past 3000 years, for example, the general evidence suggests that the northeastern portion of North America has become cooler and more moist. Over the past several hundred years, however, particularly during the first half of the present century, there is evidence for a moderating trend. There is general agreement that there has been a systematic fluctuation in recent global climate characterized by a net worldwide warming of approximately 0.5°C between the 1880s and the early 1940s. Warming has generally continued over the past three decades.

The regulation of global climate is complex and incompletely appreciated. Numerous hypotheses have been proposed to explain the forces responsible for the variability of climate. The most plausible of these include variations of the solar constant, changes in solar activity, passage of the solar system through an interstellar gas-dust cloud, variation in the velocity of the earth's rotation, gigantic surges of the Antarctic ice sheet, changes in the earth's orbital parameters, and alterations in the interactions between glaciers and oceans. Climate may respond rapidly and dramatically to small changes in these independent variables.

Added to this complexity and uncertainty is the suggestion that the activities of human beings, particularly land use activities and atmospheric contamination, are currently influencing global and regional climates. Numerous trace gases of the atmosphere, including water vapor, carbon dioxide, methane, nitrous oxide, halocarbons, and ozone (greenhouse gases), have strong infrared absorption bands. As a result, these gases can have a significant effect on the thermal structure of the atmosphere because they absorb within the 7- to $14\text{-}\mu\text{m}$ atmospheric window, which transmits most of the thermal radiation from the surface of the earth and troposphere to space. Presumably a primary result of more carbon dioxide and other "greenhouse" gases in the atmosphere will be warming. While incoming solar radiation is not absorbed by carbon dioxide and these trace gases, portions of infrared radiation from the earth to space are. Over time, the earth will become warmer. While the forces controlling global temperature are varied and complex, as suggested, the increase of 0.5°C since the mid-1800s is generally agreed to be at least partially caused by increased carbon dioxide.

General circulation models, widely used to predict future climates, are numerical models of the earth atmosphere system that solve the basic equations for atmospheric motion and provide boundary conditions of the earth and ocean. General circulation models divide the landscape into a series of regions called *grid boxes*. Each grid box consists of a series of layers, which represent land, ocean, and layers of the atmosphere. Global weather is simulated using difference equations, which detail the physics and dynamics of energy and material movement among the boxes. To evaluate the climatic change hypotheses, models are initially run with current atmospheric conditions. They are then run with altered atmospheric trace

gas concentrations (for example, carbon dioxide) to simulate a new climate. The difference between these two equilibrium climate simulations provides an estimate of how the climate system may change. Most general circulation models predict warming and overall intensification of evaporation and precipitation in the warmer climate regimes of doubled atmospheric carbon dioxide.

Using a mid-range scenario of driving variables, an increase in global mean surface air temperature relative to 1990 of about 2 °C by 2100 has been estimated. Under any scenario, the average rate of warming will probably be greater than any seen in the past 10,000 years (IPCC, 1996). General circulation model predictions of the change in the hydrologic cycle with doubling of atmospheric carbon dioxide are not clear. While precipitation is generally estimated to increase, warming will intensify evaporation. As a result, soil moisture may not increase with warming; it may even decrease. The movement of water into and out of the soil-vegetation system has a large influence on the hydrologic cycle and is very variable regionally. Models have predicted that in the United States, portions of the Northwest could become wetter, portions of the Southern Great Plains could become somewhat drier, and portions of the Northeast could become considerably drier.

Ecosystems and Climate Change

The consequences of a warmer global climate, with even very modest changes in regional temperature and hydrologic patterns, can have profound effects on ecosystems. Natural ecosystems, as opposed to artificial ecosystems designed and intensively managed by humans, may be the most vulnerable to climate change. We are least able to intervene and facilitate adaptations of natural ecosystems because of their expansiveness, our limited knowledge about fundamental ecological processes, and the absence of effective global institutions to assume responsibility for adaptations.

A shift in climate zones may exceed the ability of vegetation, for example grassland, savanna, or forest systems, to adapt through migration. If climate zones shift hundreds of miles over the next century, rates of vegetative dispersal and colonization, which are on the order of tens of miles in a century, may be inadequate to maintain present-day ecoregion patterns. With regard to terrestrial ecosystems, climate change may also adversely influence habitats by changing patterns of major stressor groups including fire regime, drought regime, and insect and disease relationships.

Alteration of ecosystems could lead to a change in species diversity, including a loss of species. The potential for migration of plants and animals to new suitable habitats is not known, but barriers such as water bodies, roads, or development could impede migration. Isolated ("island") species may find themselves in climate zones that are no longer suitable for their survival.

Montane species, unless they can migrate to higher elevations, may face extirpation or extinction. A study of a 3 °C warming in the Great Basin National Park in eastern Nevada concluded that it would cause 20 to 50 percent of species in individual mountain ranges to go extinct (Murphy and Weiss, 1992).

Forests

Tropical montane cloud forests are unique systems due to their dependence on regular cycles of cloud formation for their existence. Still *et al.* (1999) have simulated environmental conditions for such forests at CO₂ doubling and found that a combination of reduced cloud contact and increased evapo-transpiration could threaten the persistence of these systems. Pounds *et al.*, 1999 have, in fact, provided evidence that alterations in bird, reptile, and amphibian communities in the highland forests at Monteverde, Costa Rico, have occurred and may be related to recent increases in air temperature.

The vulnerability of forest ecosystems to climate change is a function of the forest location, biology, and human management activity. Forests at greatest risk will generally be those located in the northern portions of temperate latitudes. Altitude, proximity to continental margins, and distance from large water bodies will be important influencing factors. Plant species that are able to use increased CO₂ efficiently will have an advantage over other species. Similarly, species that distribute seeds widely may fare better under climate change. A mixed-species forest may tolerate a wider variety of changes than would a single-species forest. Individual plants with a low tolerance for climate fluctuations would be least adaptable to ongoing climate change. Individual populations with little genetic diversity among plants might prove to be at greatest risk of long-term decline. The most intensively managed industry and private forest land may be least at risk of catastrophic loss or long-term decline because mitigation efforts to reduce such effects will be undertaken. Many private forest managers have both the financial incentive (and resources) and the latitude to protect against extensive loss from climate-related threats. They can use several available techniques: short rotations to reduce the length of time a tree is exposed to an unsuitable climate; planting better-adapted varieties developed through selection, breeding, or genetic engineering programs to reduce vulnerability; and thinning, weeding, pest management, irrigating, improving drainage, or fertilizing to improve general health (Table 1).

The first observable effects of climate change on ecosystems will not be so much climate related as weather related. The near-term effects of climate change will be driven by changes in weather extremes and mediated through those stressors that have always been the primary controllers of ecosystem structure and health: insects, disease, wind, and fire. Even in regions where productivity may be ultimately improved, the transition period could be extended and punctuated by sudden dieback and decline. Forest ecosystems are complex, long-lived systems that can only slowly adjust to climate but that can suddenly be threatened by weather-related stresses.

The near-term response of forest systems to climate change will involve complex reactions to new averages, new patterns, and new extremes in weather variables. Some forest species that are specialized to current climate conditions may not thrive. Altered patterns of exposure to high and low temperatures could mean that winter chilling requirements will not be met. Flowering, seed-formation, and seed-dispersal processes could be disrupted, especially if pollinators do not

Table 1 Forest ecosystem vulnerability to climate change caused by alteration of the global carbon cycle

<i>Forest location</i>	<i>Forest biology</i>	<i>Forest management</i>
Higher latitude	Small, fragmented range	Fragmented forests
Higher elevation	No or few migration corridors	Less-diverse forests
Continental interior	Low genetic variance	High stand density
Maritime sites	Low species diversity	Inappropriate species
Forest-range boundaries	Genetically specialized to site	
Low-productivity sites	History of widespread dieback	
High-fire-risk sites	Heavy seed	
Drier sites		

Table 2 Forest vulnerabilities of selected United States forest systems to changes resulting from climate alteration

<i>Region</i>	<i>Tree</i>	<i>Potential stressors/key climate factor and vulnerability</i>
Northeast/North Central	Maple	Insect defoliators/warm, dry weather <i>Armillaria</i> (root decay)/drought Deep root freezing/lack of winter snow cover
Southeast	Loblolly pine	Vulnerability: High potential for damage with warmer temperatures; drier conditions Southern pine beetle/prolonged hot, dry weather Fungus (fusiform rust)/warm, moist weather Fire (favors longleaf or shrub)/warm, dry weather Storm damage/increase in coastal storms Vulnerability: Potential for much warmer weather (with increase or decrease in precipitation) to reduce productivity.
Rocky Mountain/Pacific Southwest	Ponderosa pine	Borers, bark beetles/drought Fire/drought or lightning Vulnerability: Resistant to near-term climate change, though productivity may decrease
Pacific Northwest (Coastal)	Douglas fir	Most stressors not strongly weather related Vulnerability: Resistant to near-term climate change, though productivity may decrease
Alaska	Spruce	Spruce beetle/warm weather (speeds insect development), moisture problems, erratic freezes Vulnerability: High potential for rapid effects because climate plays pervasive role.

adjust to changing conditions. With longer growing seasons, trees might add more “light” earlywood relative to the “dense” latewood that forms at the end of the growing season. This would mean a lower-quality wood for structural lumber and higher costs for pulp mills. Changes in early growing season weather conditions, particularly moisture and frosts, may affect the establishment of seedlings. Warmer and moister weather might favor the spread and boost the significance of certain fungal diseases and insect pests. Elsewhere, the drying effects of higher temperatures could be especially damaging, especially where the frequency of drought is increased. Associated with droughts would be higher risks of secondary threats from forest fires and insects. Insect damage may increase, for example, if insect pests produce more generations or persist longer during the tree-growing season.

The initial effects of climate change will not at first be easily recognized as distinct from the effects of the normal regulators of forest growth and development. The potential initial effects of climate change can be illustrated by current weather-related stresses on selected highly valued tree species in several regions of the United States. These potential vulnerabilities, by region, are presented in [Table 2](#).

Coastal-Marine

Coastal zones are very productive ecosystems, very rich in species, and very perturbed by human activities. In addition, they may be at substantial risk from global climate change. These risks stem from changes in water column temperature or other water quality parameters, change in ocean current dynamics, and alterations of sea level.

Widespread extinctions are not likely, but expansive alteration of community distributions and composition are possible. Most marine organisms, in contrast to long lag times discussed for forest ecosystems, have high mobility, large ranges, high fecundity, and rapid growth rates. As a result, they may be able to adapt to climate change more efficiently than terrestrial systems ([Ray et al., 1992](#)).

Coral reefs are the most species rich of marine ecosystems. These reefs are largely restricted to tropical waters, but generally do not occur where temperatures exceed 30 °C for extended periods. As a result, even small increases of 1 to 2 °C for the surface waters of tropical oceans could have important implications for reef ecosystems.

Temperate latitude estuarine and tidal wetland and marsh ecosystems will be at substantial risk if sea level increases

over the next several decades. For each cm of rise in sea level, beaches may erode 1 m landward. Storm surges, a major eroding force, will increase, especially in areas of modest shore slopes. For every 10 cm rise, saltwater wedges in estuaries and tidal rivers may advance 1 km. Sea-level rise will also increase salinity intrusion into coastal freshwater aquifers (NAS, 1987).

Fresh Water

Freshwater ecosystems will present challenges for native biota if global climate continues to warm. Changes in precipitation and evapotranspiration can combine to offset surface-water and groundwater quantity and quality, low and high flow conditions, and drought and flood frequency. In addition, water column temperature is a key determinant of habitat quality. Stream temperature, for example, is a fundamental habitat criterion for all salmonids. For example, the habitat of brook trout in the southern Appalachian Mountains is already fragmented by natural and anthropogenic forces. Climate warming would directly and indirectly fragment and limit brook trout range even more via temperature change and hydrologic cycle change. Flebbe (1997) used geographic information system techniques to evaluate warming effects on brook trout distributions. Both suitable area and stream length for these fish were seen to decrease as suitable habitat is increasingly restricted to mountaintops.

Perturbation of the Nitrogen Biogeochemical Cycle

The atmosphere is 78 percent by volume elemental nitrogen (N_2). The N_2 molecule is extremely stable and only very

specialized pathways allow this nitrogen to be made available to the biota. Elemental nitrogen is incorporated into chemically bound forms (fixed) by biochemical processes mediated by microbes. High-energy lightning discharges can produce nitrogen oxides. The nitrogen incorporated in the biota is mineralized to the inorganic form during the decomposition of biomass. The production of gaseous N_2 and N_2O by microorganisms and the evolution of these gases to the atmosphere completes the nitrogen cycle through a process called denitrification (Figure 2). While elemental nitrogen and elemental oxygen (O_2) do not react at ambient temperature and pressure conditions in the troposphere, they do react at the elevated temperatures of combustion processes. As a result, all anthropogenic activities involving combustion, from industrial and power generation combustion to automobile and truck engine combustion, function to inject large amounts of nitrogen oxides (NO and NO_2) to the lower atmosphere. These oxides are extremely important pollutants and have substantial potential significance for biological diversity. Nitrogen oxides present risks to the biota directly in the form of acid rain and nitrogen saturation and indirectly as they act as precursors for the formation, along with hydrocarbons, of ozone in the troposphere.

Acid Rain

Acid rain is appropriately described as an old environmental problem with a new image. Acid rain, more than any other environmental contaminant, has focused societal concern on ecosystem toxicology. Natural rain, including precipitation in

Figure 2 The global nitrogen cycle. The storage (numbers without arrows) and the annual flows (numbers with arrows) are shown for the global system. The units are 10^{12} g nitrogen.

relatively clean or unpolluted regions, is naturally acidic, with a pH in the range of 5.0 to 6.0. This natural acidity results from the oxidation of carbon oxides and the subsequent formation of carbonic acid. Formic and acetic acids, originating primarily from natural sources, may also contribute minor amounts of acidity to precipitation.

In regions downwind from electric-generating power stations employing fossil fuels, industrial regions, or major urban centers, precipitation can be acidified below pH 5.0. Precipitation with a pH less than 5.0 is designated acid rain. This human-caused acidification of precipitation results primarily from the release of sulfur dioxide (SO_2) and nitrogen oxides (NO and NO_2) from smokestacks and tailpipes. The sulfur and nitrogen oxides are subsequently oxidized to sulfate (SO_4^{2-}) and nitrate (NO_3^-), hydrolized, and returned to earth as sulfuric (H_2SO_4) and nitric (HNO_3) acids. This additional acidification of precipitation by human activities can readily reduce the pH of precipitation in downwind regions to between 4.0 and 5.0 on an annual average basis. Individual precipitation events that have a pH in the 3.0 to 4.0 range are not uncommon.

The atmosphere deposits acidity onto the landscape both during and in between precipitation events. In the latter case, termed dry deposition in contrast to wet deposition, the acids are delivered in the gas phase or in association with fine particles (aerosols). Acid deposition is a term that includes acid delivery in the form of precipitation (rain, snow, fog, and cloud moisture) plus dry deposition. In view of the importance of both wet and dry deposition in acid transfer from the atmosphere to the biosphere, acid deposition is a much more appropriate descriptor than acid rain.

Aquatic Ecosystems

The pH range for undisturbed lakes and streams with full compliments of native biota, especially selected finfish species important to humans, typically is within the range of 6 to 8. Lakes and streams with a $\text{pH} < 6$ do occur naturally. Land use practices, for example, conversion from agriculture to forest in the watershed of a lake can, over time, also cause lake acidity to increase. Aquatic resources acidified from the input of acid rain are also well documented, particularly in the northern United States, eastern Canada, and Scandinavia.

Fortunately, most surface waters in the United States have sufficient buffering (acid-neutralizing) capacity to be resistant to acidification via atmospheric deposition. In the instance of high acid deposition inputs and poorly buffered aquatic systems, however, declines in water column pH can be caused by acid rain. In the mid-1980s a National Surface Water Survey was conducted in areas of the United States known to contain lakes and streams with little capacity to neutralize acids. This survey identified the Adirondaks and mid-Atlantic Highlands region as having both sensitive aquatic resources and high levels of acid deposition.

The adverse response of aquatic biota to acidification is very well documented (NAPAP, 1991). Sensitive species may be stressed or lost at small increases in acidity.

Acid-sensitive mayfly and stonefly species can be impacted at pH levels near 6.0 and sensitive finfish species, for example,

fathead minnows, can be lost at pH 5.6 to 5.9. Acid sensitive phytoplankton, zooplankton, and benthic macroinvertebrate species may also be lost. Acid-tolerant species may increase significantly with acidification. Survival of fish in acidic waters is primarily related to pH level, inorganic chemistry of aluminum, and the concentration of calcium. Other relevant considerations include food web effects, spatial and temporal variation in exposure to acidity and aluminum at various life stages, and behavioral avoidance. Critical pH levels for selected aquatic organisms are presented in **Figure 3**.

Forest Ecosystems

The adverse impact of acid deposition on forest systems is focused on the montane forests of eastern North America. Prevailing wind patterns and the importance of cloud moisture delivery of acidic materials places these high-elevation forests at special risk. Both morbidity and mortality of large numbers of forest trees are easily documented in montane forests. Acid deposition may be directly or indirectly involved in this symptomology. The primary mechanisms of proposed effects are foliar weathering, foliar and soil nutrient leaching, aluminum and heavy metal soil toxicity, and predisposition to greater microbial disease and insect activity (Smith 1989, 1990).

Nitrogen Saturation

For forests in temperate latitudes, the input of nitrogen via atmospheric deposition may approximate 0.5 kg N ha/yr in clean atmospheric conditions. This low input combined with acidic organic soils in cool climates with high lignin content and slow rates of decomposition and, therefore, slow internal nitrogen turnover cause most forest systems to be nitrogen deficient. Numerous forests provided with supplemental nitrogen exhibit enhanced growth rates indicating that they were nitrogen limited prior to fertilization. In forest locations with less than clean atmospheric conditions (acid rain), forests may receive up to 27 kg N ha/yr if both dry and wet deposition sources are inventoried. At elevated levels of atmospheric input and normal dynamics of internal nitrogen cycling, forests can be fertilized by nitrogen in acid rain and exhibit increased growth and productivity.

If high levels of nitrogen deposition persist, however, nitrogen availability may reach a level that exceeds the vegetative and microbial nitrogen demand and cause the system to enter a condition designated nitrogen saturated. If sustained, evidence has been presented to indicate that nitrogen saturation can be detrimental to forest systems and lead to decreases in foliar biomass, imbalances in foliar nutrient concentrations, enhanced nitrification, and possibly tree morbidity and mortality. Nitrogen saturation of forest soils may lead to high levels of nitrate in stream waters of forest catchments. Excess nitrogen loading of surface waters can impose stresses on aquatic species.

Nitrogen Oxides as Tropospheric Ozone Precursor

In the presence of sunlight nitrogen dioxide is dissociated and forms equal numbers of nitric oxide molecules and oxygen

Figure 3 Critical pH levels for selected aquatic organisms where the American toad, wood frog, leopard frog, and spotted salamander are shown in the embryonic stage, and the crayfish, mayfly, clam and snail are selected species.

atoms. The oxygen atoms rapidly combine with molecular oxygen to form ozone. This ozone then reacts with the nitric oxide, on a one-to-one basis, to reform nitrogen dioxide. The steady-state concentration of ozone that is produced by this cycle is very small. When hydrocarbons, aldehydes, or other reactive atmospheric constituents are present, however, they can form peroxy radicals that oxidize the nitric oxide back to nitrogen dioxide. With reduced nitric oxide available to react with the ozone, the latter may accumulate to relatively high concentrations.

High concentrations of ozone are toxic to vegetation. Morbidity and mortality of agricultural and forest plants caused by ozone are well documented. California provides numerous examples of ozone stress on wildland ecosystems. In southern California the predominant native shrub land vegetation consists of chaparral and coastal sage scrub. The former occupies upper elevations of the coastal mountains, extending into the North Coast ranges, east to central Arizona, and south to Baja California; the latter occupies lower elevations on the coastal and interior sides of the coast ranges from San Francisco to Baja California. Westman (1979) applied standard plant ordination techniques to these shrub communities to examine the influence of air pollution. The reduced cover of native species of coastal sage scrub documented on some sites was statistically indicated to be caused by elevated atmospheric ozone. Sites of high ambient ozone were also characterized by declining species richness.

Ponderosa pine is one of five major species of the "mixed conifer type" that covers wide areas of the western Sierra Nevada and the mountain ranges, including the San Bernardino Mountains, in southern California from 1000 to 2000 m

elevation. Other species represented include sugar pine, white fir, incense cedar, and California black oak. The response of these five major tree species to ozone in the San Bernardino National Forest is variable as shown by field surveys and seedling exposures. Ponderosa pine exhibits the most severe foliar response to elevated ambient ozone. An aerial survey conducted by the USDA Forest Service indicated 1.3 million ponderosa (or Jeffrey) pines on more than 405 km² (100,000 acres) were stressed to some degree. Mortality of ponderosa pine has been extensive. White fir has suffered slight damage, but scattered trees have exhibited severe symptoms. Sugar pine, incense cedar, and black oak have exhibited only slight foliar damage from oxidant exposure. A 233 ha study block was delineated in the northwest section of the San Bernardino National Forest in order to conduct an intensive inventory of vegetation present in various size classes and to evaluate the healthfulness of the forest. Ponderosa pines in the 30 cm diameter class or larger were more numerous than other species of comparable size in the study area. These pines were most abundant on the more exposed ridge crest sites of the sample area. Mortality of ponderosa pine ranged from 8 to 10 percent. The loss of a dominant species in a forest ecosystem clearly exerts profound change in that system. Miller (1989) concluded from his investigations that the lower two-thirds of the study area will probably shift to a greater proportion of white fir. It was judged that incense cedar will probably remain secondary to white fir. Sugar pine was presumed to be restricted by lesser competitive ability and dwarf mistletoe infection. The rate of composition change was deemed dependent on the rate of ponderosa pine mortality. The upper one-third of the study area, characterized as more

environmentally severe due to climatic and edaphic stress, supports less vigorous white fir growth. Following the loss of ponderosa pine in this area, sugar and incense cedar may assume greater importance. Miller judged, however, that the natural regeneration of the latter species may be restricted in the more barren, dry sites characteristic of the upper ridge area. California black oak and shrub species may become more abundant in these disturbed areas. Generally, the data support the hypothesis that forest succession toward more tolerant species such as white fir and incense cedar occurs in the absence of fire. In the presence of fire, pine may be favored by seedbed preparation and elimination of competing species.

The changes in forest composition caused by ozone in this southern California forest have created a management concern, as well as ecological change, because the forest is intensively used as a recreational resource and the loss of ponderosa pine is judged to reduce the aesthetic qualities of the forest.

Perturbation of the Sulfur Biogeochemical Cycle

The natural sulfur cycle is complex in that it involves several gaseous species, poorly soluble minerals, and several species in solution (Figure 4). Sulfur enters the atmosphere from natural sources as hydrogen sulfide (H_2S) from active volcanoes and the decay of organic matter in anaerobic environments (swamps, tidal flats), sulfur dioxide (SO_2) from active volcanoes, and particles of sulfate salts (e.g. ammonium sulfate) from sea spray. Approximately one-third of all sulfur compounds and 99 percent of the SO_2 reaching the troposphere

comes from human combustion activities. The combustion of coal and oil for the production of electricity and the smelting of metal-bearing ores have historically been major sources of SO_2 to the atmosphere.

The industrial and energy sector release of SO_2 over multiple decade timescales has reduced biological diversity in local environments surrounding point source facilities in many parts of the world.

In North America, for example, we can cite the cases of Ducktown, Tennessee, and Sudbury and Wawa, Ontario. The Ducktown, Tennessee, area consists of approximately 243 km^2 (60,000 acres) and was originally covered with southern deciduous forest. Mining operations were initiated in the basin in 1850 and smelting operations were most active between 1890 and 1895. By 1910 gross forest simplification resulting from excessive sulfur dioxide had created three new vegetative zones surrounding Ducktown. In a 27 km^2 (10.5 mile²) area closest to the source, vegetation was devastated and largely eliminated. All trees and shrubs were destroyed, and only a few, isolated islands of sedge grass occurred in the outer portions of this zone. A belt of grassland ecosystem, 68 km^2 (17,000 acres) in size, surrounded the barren zone. The principal grassland species was broomsedge. A transition zone of somewhat indefinite boundary and consisting of approximately 120 km^2 (30,000 acres) was located beyond the grassland. Few trees were located along the inner edge of the transition zone. Sassafras, red maple, sourwood, and post oak were common in the middle of the transition forest. The uninfluenced forest beyond the impact of the smelter consisted principally of mixed oaks, hickory, dogwood, sourwood, black tupelo, and some eastern white pine. The distance of

Figure 4 The global sulfur cycle.

vegetative impact extended 19 to 24 km (12 to 15 miles) to the north and approximately 16 km (10 miles) to the west of the smelter. Eastern white pine damage was recorded 32 km (20 miles) from the industry.

Sheet and gully soil erosion has been excessive in the acutely damaged inner zone. Micrometeorological changes in the inner zone relative to the surrounding forest have been substantial; summer air temperature averages are 1 to 2 °C higher, while the winter air temperature averages 0.3 to 1 °C lower, the soil temperature is 11 °C higher in the summer; the wind velocities are five to 15 times higher and rainfall is consistently lower.

Reforestation of Copper Basin has not been rapid due to severe erosion, low soil nutrients and moisture, and high winds. Recent reforestation efforts have employed both pine and hardwood species (Smith, 1990).

In the Sudbury area, a century of sulfur dioxide fumigation, copper and nickel particulate deposition, fire, soil erosion, and increased frost action have interacted to create 10,000 ha (25,000 acres) of barren land and 36,000 ha (89,000 acres) of stunted, open birchmaple woodland. Three large nickel and copper smelters have historically discharged several thousand tons of sulfur dioxide daily into the surrounding atmosphere. Sulfur dioxide emissions from this area have historically approximated 10% of the North American sulfur dioxide total and 25% of the smelter total. Extensive simplification of the mixed boreal forest ecosystem surrounding this region has occurred primarily via the mortality of eastern white pine throughout a 1865 km² (720 square mile) area to the northeast of the Falconbridge, Copper Cliff, and Coniston smelters. Acute impact on balsam has been recorded in excess of 40 km (25 miles) from the source of sulfur dioxide. Red oak, red maple, and red-berried elder are more tolerant and may exist in disturbed forests as close as 1.6 km (1 mile) to the smelters. Morbidity and mortality of forest trees in the Sudbury region continued to spread at least until the construction of the world's tallest smokestack of 403 m (1250 feet) at Copper Cliff in 1972 and the closing of the Consiton smelter also in 1972.

Soil erosion has followed the destruction of surrounding forest ecosystems. Rainfall has been made highly acidic, commonly less than pH 3.0 in the early 1970s. Elevated nickel and copper concentrations in soils have been recorded to distances of 50 km (31 miles). Eroded sediment, contaminated with trace metals, has contaminated area lakes and water resources. This contamination, along with acidification of surface waters, has resulted in numerous aquatic species extirpations.

Forest destruction in the vicinity of an iron smelter in Wawa, northern Ontario, exhibits a more discrete pattern, one smelter relative to three, and a shorter history of impact resulting in less equilibration of vegetative response than in Sudbury. The Wawa smelter initiated operations in 1939 (significantly expanded in 1949) and has released as much as 100,000 tons of sulfur dioxide annually to the surrounding atmosphere. Negative impact is primarily confined to a strip northeast from the plant in the direction of the prevailing wind. Symptoms of sulfur dioxide damage may be observed for at least 32 km (20 miles) to the northeast. The mixed boreal forest in the Wawa area consists mainly of white spruce, black spruce, balsam fir, jack pine, white cedar, larch, and

white pine in the dominant layer. Mountain maple and *Pyrus decora* are common in the understory.

Trace Pollutants of Global Importance

Persistent organochlorine compounds, including the polychlorinated biphenyls (PCBs) and organochlorine pesticides, are among the most important anthropogenic contaminants with global status. These pollutants biomagnify in food webs and have resulted in acute and subtle ecotoxicological effects in aquatic and terrestrial organisms. Despite increased regulation and reduced use, urban and industrial areas remain a significant source of PCB pollutants. The insecticide DDT has seen reduced or terminated use in Canada, the United States, and western Europe, but increased use in Mexico, Central America, India, and eastern Europe. Both PCBs and DDT (including its breakdown products DDD and DDE) can enter the atmosphere via volatilization, or in combination with aerosols, and be transferred from the atmosphere to the biosphere via both dry and wet deposition. Long-distance atmospheric transport and subsequent deposition have been observed to contaminate numerous ecosystems remote from primary sources including estuarine and lacustrine systems. Less research has been directed to documenting contamination of terrestrial systems, especially forests.

Northern and boreal forests develop a thick organic forest floor and in recognition of the tendency of trace organic pollutants to bind to the surface (adsorb) or penetrate (absorb) into soil particles, it is especially important to examine these organic soils for trace pollutants. Such an examination of forest floors of remote northern New England hardwood and montane forest soils has revealed the presence of numerous PCBs and DDT and its breakdown products (Smith *et al.*, 1993).

While the soil and water column concentrations of these pollutants are relatively low, their low water solubility but high lipid solubility allow the processes of bioaccumulation and bioconcentration to elevate these potential toxics to levels sufficient for adverse biological effect (Allen-Gil *et al.*, 1997a, b). These elevated concentrations can cause change in community composition (Ferraro and Cole, 1997).

Conclusion

Human beings have—through their efforts to generate electricity, manufacture things, and transport themselves and their goods—managed to alter major biogeochemical cycles of the earth. In addition, the manufacture and use of a variety of environmentally persistent chemicals have resulted in the global circulation of materials with potentially biologically toxic properties.

Perturbation of the carbon cycle via increased combustion and deforestation and the resulting global warming presents a high risk to biological diversity. Continued global warming will result in species extirpations and possible extinctions as we progress to the middle of the twenty-first century. Changes in the nitrogen cycle caused by human activities are less impressive than the alteration of the carbon cycle but still have

the extended-term potential to change both terrestrial and aquatic ecosystems and to result in species losses. Changes in the sulfur cycle, while substantially less widespread than alterations in the carbon and nitrogen cycles, have proven historically to have been sufficient to cause numerous local extirpations in the vicinity of point sources.

The atmosphere, while highly structured (layered) horizontally, has no vertical partitions. As a result, the injection of chemically persistent toxins anywhere in the world means they may begin a journey of global circulation and eventual deposition. Accumulation of these toxins via environmental media or food-web exposure can place certain species at risk of loss from receiving environments.

Pollutants of global importance and the ability of humans to alter fundamental biogeochemical cycles must be recognized as important mechanisms for the loss of biological diversity. Efforts to monitor the trends of both pollutants and major chemical cycles along with species at risk must be made a high priority for contemporary environmental management. The loss of species and communities must be recognized as a primary reason for increased international efforts to reduce the production and release of pollutants.

Glossary

Family planning The conscious effort of couples to regulate the number and spacing of births through artificial and natural methods of contraception. Family planning connotes conception prevention to avoid pregnancy and abortion, but it can also refer to the efforts of couples to induce pregnancy.

Fertility The actual reproductive performance of an individual, a couple, a group, or a population measured by a variety of rates, including the crude birth rate (number of births per 1000 population) and total fertility rate (TFR).

Life expectancy The average number of additional years a person could expect to live if current mortality trends were to continue for the rest of that person's life, most commonly cited as life expectancy at birth.

Mortality Deaths as a component of population change. Measures include the crude death rate (number of deaths per 1000 population).

Population change An increase or decrease in the size, composition, or distribution of a population resulting from the interaction of births, deaths, and migration in a population in a given period of time.

Population composition The distribution of a population, usually by age and sex, measured by the

number and proportion of males and females in different age groups.

Population momentum The tendency for population growth to continue beyond the time that replacement-level fertility has been achieved because of the relatively young age structure of the population.

Replacement-level fertility The level of fertility at which a couple replaces itself in the population. In low-mortality countries, a TFR of 2.1 is considered replacement because some women will die before the end of their childbearing years.

Stable population A population with an unchanging rate of growth and an unchanging age composition as a result of age-specific birth and death rates that have remained constant over a sufficient period of time. Zero population growth is a special case of population stabilization in which no growth occurs because the number of births and deaths are the same.

TFR The average number of children who would be born to a woman during her lifetime if she were to pass through her childbearing years conforming to the age-specific fertility rates of a given year.

History of Human Population Growth

For much of our history, humans have struggled to survive. By AD 1, perhaps 300 million people lived on the Earth, a paltry total after millions of years of human existence. For most of the next 2000 years, population growth was exceedingly slow. High birth rates were often offset by frightful mortality from wars, famines, and epidemics. The bubonic plague, for example, reduced the populations of China and Europe by one-third in the fourteenth century.

Despite dramatic spikes in mortality rates, the number of births exceeded the number of deaths during the seventeenth and eighteenth centuries and population growth proceeded at a slightly faster pace. As shown in [Figure 1](#), world population was about 790 million in 1750 and reached 1 billion in approximately 1800.

During the next century, in Europe and in a few other areas throughout the world, better hygiene and public sanitation reduced the incidence of disease. Expanded commerce made food supplies more widely available and improved nutrition. The wild fluctuations in mortality of previous centuries began to recede, and life expectancy began a slow rise. Population grew more quickly and more steadily. Total world population was nearly 1.7 billion by the beginning of the twentieth century and reached 2 billion within the next 30 years.

The nineteenth-century surge of population growth occurred primarily in the more-developed countries. The population of Europe more than doubled between 1800 and 1900, whereas the population of North America increased nearly 12 times – fueled by immigration from Africa and Europe. In 1800, approximately one-fourth of the world population lived in the now more-developed regions of Europe (including Russia), Japan, and North America, but this share increased to about one-third by 1900.

Less-developed countries grew more slowly than the more-developed countries in the nineteenth century, but they already held the bulk of the world's inhabitants. Asia, dominated by China, had 62% of the world population in 1800, and Africa had 11%. Latin America and the Caribbean accounted for only approximately 2% of the world's population. Like North America, Latin America witnessed most of its population growth in the twentieth century.

Demographic Transition

The improvement in human survival and the consequent explosion of population growth marked the beginning of the shift from high to low mortality and from high to low fertility, which is known as the “demographic transition.” This shift occurred throughout Europe, North America, and many other

Figure 1 Population growth in more-developed and less-developed countries, 1750–2000.

areas in the nineteenth and early twentieth centuries. It gave rise to the dominant model of demographic change, which most demographers assume applies to all countries. In the classic demographic transition, the trend of high birth and death rates (and minimal population growth) is disrupted by a long-term decline in mortality. Mortality rates eventually stabilize at low levels. Birth rates also begin a long-term decline and decrease to about the same level as mortality rates. With birth and death rates at similar low levels, the equilibrium of slow population growth is regained.

The pace of change in a country will vary depending on its culture, level of economic development, and other factors. As countries pass through the various stages of the transition, population growth from natural increase (birth rate minus death rate) accelerates or declines depending on the gap between the birth rates and death rates. Not all countries will follow the same path to low fertility and low mortality as did European countries. Also, there may be additional stages of transition that have not been identified, for example, long-term population decline. However, the demographic transition theory provides a useful framework for assessing demographic trends and projecting future population size.

Population Change: 1900–1950

When the twentieth century began, more-developed countries were entering a new stage of the demographic transition. In 1900, life expectancy at birth was 47 years in the USA and between 45 and 50 years in Europe, Japan, and Australia, which was a slight increase from an average of about 40 years during the nineteenth century. A revolution in health had already begun and life expectancy would reach unimaginably high levels by midcentury. These improvements in health reflected scientific advances of the previous century. Louis Pasteur, Robert Koch, and others had identified disease-causing

“germs,” and Joseph Lister introduced antiseptic practices that were eventually adopted by hospitals. Mortality was also declining because of better personal hygiene and public sanitation projects that removed garbage and sewage from city streets and provided safer drinking water. Death rates for infectious diseases began to decrease well before vaccines and antibiotics were widely available.

Infants and young children benefited most from this health revolution. In the more-developed countries, the infant mortality rate (IMR; number of deaths to infants younger than 1 year of age per 1000 births) was approximately 200 in the 1800s – approximately two of every 10 babies died before their first birthday. In the early 1900s, the IMR decreased below 100 in the USA and many European countries. It was lower than 50 in nearly all these countries by the 1950s. The life expectancy at birth in the USA increased to 56 years by 1920 and to 68 years by 1950. Average life expectancy was even higher in some European countries by 1950.

Although birth rates had decreased during the latter part of the nineteenth century, women were still having relatively large families in 1900. According to the United Nations (UN), an American woman had four to five children on average; a European woman had somewhat fewer. Fertility decline quickened after 1900.

During the same period, most of Africa, Asia, and Latin America were still in the predemographic transition stage of high mortality and high fertility.

Population Change: 1950–2010

The second half of the century and the first decade of the twenty-first century brought many new demographic trends and patterns. The more-developed countries completed their transition to low mortality and low fertility and to the lowest low fertility and reversal; for example, in Bulgaria, the fertility

went down to 1.1 children per woman in 1997, lowest low among 27 European countries, and later increased (reversal) to 1.6 children per women in 2009. Population growth slowed and even turned negative in a few countries. Populations grew older. The more-developed countries also experienced sometimes disruptive changes associated with baby booms and baby busts, crises in health, and waves of immigrants and refugees.

In less-developed countries, the second half of the century brought decades of rapid population growth and swelling streams of migrants from rural to urban areas. Some countries appeared to be rushing through the various stages of the demographic transition, whereas others appeared to be following a new path of demographic change.

Mortality, Fertility, and Natural Increase

In Europe, population growth accelerated as countries recovered from the devastating effects of World War II. The rapid decline in death rates of the early part of the century slowed considerably in part because infant and childhood mortality had already decreased to very low levels. By 1975, the IMR was 10 in Japan, 16 in USA, and 15 in much of Europe. According to the US Census Bureau, US life expectancy increased by less than 10 years in the second half of the century, from 68 years to 76 years, after increasing by more than 20 years during the first half.

After World War II, “baby booms” were commonplace in Europe, although they were more modest than the baby boom that occurred in the USA between 1946 and 1964. However, by the mid-1970s, total fertility rates (TFRs; which reflect the average number of children per woman) in many European countries had decreased below two, the level at which a couple replaces itself in the population. A TFR must be slightly higher than 2.0 (about 2.1 in low-mortality countries) to reach replacement level because some women will die before the end of their childbearing years. When the TFR remains lower than two for a prolonged period, populations may experience a natural decrease because deaths will outnumber births.

European fertility had decreased during the 1930s Great Depression, but in the mid-1980s, TFRs sank to record low levels and showed little sign of recovery. By the late 1990s, the TFR was 1.2 or less in Belarus, Bulgaria, the Czech Republic, Estonia, Italy, Latvia, and Spain.

The fertility decline began in Western Europe during a period that saw delayed marriage, more divorce, high inflation, and an increase in the percentage of women attending college and working outside the home. These same social and economic factors favored lower fertility in the USA, in which the TFR reached an all-time low in 1976 at 1.7 children per woman. Below-replacement fertility also occurred in Eastern Europe and the former Soviet Union after 1990.

Two decades of low fertility has halted population growth in nearly all of Europe and Japan. In many cases, a decline in population was avoided only by the flow of immigrants from abroad. In the late 1990s, 14 European countries experienced natural decrease or fewer births than deaths each year.

Natural decrease will spread to other countries as low birth rates drastically reduce the number of people entering the childbearing ages. Although some countries have a net

population gain from immigration, this is not expected to generate enough growth to stave off eventual population decline if fertility levels continue to remain low. It is possible that TFRs will increase again in some countries as recent trends toward later marriage and childbearing stabilize and couples who delayed childbearing complete their families. However, at the end of the twentieth century, not one major industrialized country had fertility above replacement level.

Among the more-developed countries, only a few traditional immigration countries (Australia, Canada, New Zealand, and the USA) can expect significant long-term population growth. They have younger age structures and more immigration than do Europe and Japan, which contributes to momentum for continued growth.

Fertility and mortality patterns have been very different among less-developed countries in the last 61 years. Gains in life expectancy accelerated after 1950. The average life expectancy at birth in less-developed countries increased from 42 to 66 years between 1950 and 2011 according to the UN estimates. The IMR decreased from 151 to 50 deaths per 1000 births during the same period.

Average life expectancy increased to more than 60 years in East Asia and Latin America by the early 1970s and to more than 70 years by the late 2000s. The IMR decreased to about 20 in East Asia and 22 in Latin America by 2008.

Progress has been much slower in sub-Saharan Africa and South-Central Asia. In the 1950s, more than 170 infants died per 1000 births in these regions. By the 2000s, the IMR was still close to 85 in sub-Saharan Africa and was nearly 56 in South-Central Asia.

The pace of mortality decline in some areas has been slowed down by the spread of human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS), and dramatic declines in life expectancy were observed in some countries of sub-Saharan Africa; however, various national and international efforts have made it possible for life expectancy to rise in the late 2000s. Worldwide, more than 25 million people have died from HIV/AIDS since the beginning of the pandemic in the 1980s. An additional 34 million were living with HIV at the end of 2010. Most will die within the next decade. The UN agency that tracks the HIV/AIDS pandemic, UNAIDS, estimates that there are more than 7000 (down from 16,000 around 2000) new infections daily, 1100 (1600 around 2000) of which are in children (UNAIDS report on the Global AIDS epidemic, 2010)

Population Growth

The general reduction in death rates after 1950 led to explosive population growth in many less-developed countries. For the world as a whole, growth rates peaked during the 1960s and early 1970s at approximately 2% annually. The total population for less-developed countries increased from 1.7 to 5.7 billion between 1950 and 2010. Population growth would have been even higher if fertility rates had not started to decrease in less-developed countries. The pattern and pace of decline varied tremendously, depending on economic and social development, government policies, family planning use, and other factors (see [Box 1](#); [Figure 2](#)).

During the 1950s and 2000s, childbearing levels declined significantly in many regions. **Figure 3** illustrates that declines were greatest in Asia and Latin America and much smaller in sub-Saharan Africa. Despite these declines, all developing regions had TFRs above replacement level in 2011 and more than 76 countries had TFRs of 3.0 or higher.

Changing Age Profiles

Fertility, mortality, and migration trends are reflected in the age and sex profiles of the world's countries. The decades of high fertility rates in the less-developed countries meant ever-increasing numbers of young people, illustrated by the broad base of the age-sex pyramid shown in **Figure 4**. Improvements in infant mortality have also contributed to the expanding youth population. Children aged younger than 15 years comprised three-tenths of the population in the less-developed countries in 2010 and even greater proportions in some regions. In sub-Saharan Africa, children comprised nearly two-fifths (42%) of the population. Elderly people aged 65 years or older comprised only 6% of the population in all less-developed countries and 3% of the population in sub-Saharan Africa.

The base of the population pyramid for less-developed countries shows some narrowing – the result of declining fertility in many countries beginning in the 1980s. However, even with declining fertility rates, the young

age structure creates considerable momentum for future growth because the population reaching childbearing age continues to expand. Women currently have fewer children than in the past, but today there are more women having children.

Figure 2 Contraceptive methods percentages used by currently married women, aged 15–49 years, throughout the world, 2009.

Box 1 The reproductive revolution

The “reproductive revolution” was one of the most remarkable events of the second half of the twentieth century. The development of family planning methods, such as the pill and the intrauterine device (IUD), simpler sterilization techniques, and contraceptives that can be injected or implanted under the skin made it easier and safer for women to avoid unintended pregnancies. Increased access to these methods and socioeconomic changes that motivated couples to limit their family size drove the fertility declines in the last few decades. Family planning use increased from less than 10% for married women of childbearing age in the 1960s to more than 62% of this group of women in the late 2000s (**Figure 2**).

Before 1960, women's choices of family planning methods were limited to methods, such as withdrawal, rhythm, diaphragms, foams or jellies, or ineffective methods such as herbal medicines or douching. Women's options improved immensely when the pill and the modern IUD became available after 1960. In the late 2000s, approximately 23% of women worldwide relied on one of these two methods. New contraceptives, including injectables and implants, became available in many countries in the 1980s. They have become popular methods in some African countries. Female sterilization has been widely adopted in Asia and Latin America and is the most popular method worldwide. An estimated 19% of married women (or in a union) aged 15–49 years rely on female sterilization to prevent pregnancy.

The dramatic increase in family planning use caused fertility to decline much more rapidly in the less-developed countries than it had during the fertility transition in the more-developed countries. Organized family planning programs and government promotion of family planning use were important components of this phenomenon. Some experts credit family planning programs for 40–50% of the fertility decline in less-developed countries since the 1960s.

An estimated 120 million couples worldwide want to delay or prevent another pregnancy but are not using family planning. If unmarried sexually active women were included, the number would be much higher, according to survey data.

Family planning use varies widely throughout the world. For example, less than 10% of women use family planning in Mali and less than 20% use it in Afghanistan. However, more than 60% of married women use family planning in Morocco, Argentina, Indonesia, and many other less-developed countries.

The expansion of family planning services has been controversial in some countries. There have also been many obstacles to their use. Many women report that they fear adverse health effects from specific methods. Others want to practice family planning but are dissuaded by their husband's disapproval, their limited decision-making powers, or family pressures to have more children. Some methods are opposed for religious reasons. Difficulties in obtaining and transporting supplies and a shortage of trained medical personnel have also restricted access to family planning services.

Political and cultural barriers have limited access to family planning, especially for young people. In some countries, unmarried adolescents are denied access to family planning services on the assumption that such access would promote promiscuity. However, approximately 40% of girls in less-developed countries give birth before the age of 20 years. The pace of fertility decline in Africa, South Asia, and other high-fertility regions will be affected by whether young couples delay their first birth until they are in their 20s. This delay lengthens the interval between generations and lowers the average fertility. Health analysts estimate that women aged 15–19 years face twice the risk of dying from pregnancy and childbirth as do women in their 20s. In many countries, children born to mothers aged younger than 20 years are 1.5 times more likely to die before their first birthdays than are children born to mothers in their 20s.

Most less-developed countries provide family planning services. In many countries, family planning methods are also widely available from pharmacies and private health clinics. Not all women have easy access to family planning, but the expansion in the choices of methods and availability of services throughout the world during the last 50 years has been truly revolutionary.

Figure 3 Fertility decline in world regions, 1950–2011. *TFR is the average number of children a woman will have under prevailing birth rates.

Causes and Effects of Human Population Growth

The demographic processes of fertility and mortality are influenced by biological, cultural, economic, geographic, political, and social factors. These factors affect demographic processes directly and indirectly through a web of interdependent variables. Cultural traditions that encourage girls to marry at a young age, for example, can contribute to high fertility rates because women will spend more years exposed to the risk of becoming pregnant. Early marriage can also lead to higher mortality because health risks to the infant and mother are greater when childbearing starts in adolescence.

In the 1980s, demographer John Bongaarts identified four variables that account for most differences in fertility rates. These “proximate determinants” of fertility are (1) the proportion of women married or in a sexual union; (2) the percentage of women using contraception; (3) the proportion of women who cannot conceive a pregnancy, especially during the infertile period following childbirth (postpartum infecundity); and (4) the level of abortion.

The importance of each proximate determinant depends on cultural, economic, health, and social factors within a population. The proportion of women in a sexual union is partly determined, for example, by the age at marriage, the proportion of women who never marry, and levels of divorce. Cultural mores about sexual activity and childbearing outside marriage also play a role.

In societies where women marry young, and in which nearly all childbearing takes place within marriage, changes in the age at marriage can significantly affect fertility. For example, in the Arab countries of the Middle East, an increase in the average marriage age for women led to significant fertility declines in some countries.

The length of postpartum infecundity usually depends on how long women breast-feed their babies. Breast-feeding releases hormones in the nursing mother that can prevent her from becoming pregnant. Postpartum infecundity is not a significant factor in such countries as the USA, in which women usually breast-feed their babies only for a few months,

but it is important in sub-Saharan Africa and other traditional societies in which women commonly breast-feed their babies for 2 years. In most populations, contraceptive use and abortion are the primary determinants of fertility levels.

Education and poverty are among the most important influences on the proximate determinants and consequently have a strong indirect effect on fertility. Low levels of education and poverty are related, and they are also related to health and to levels of economic development, urbanization, and environmental conditions.

Education

Although researchers cannot determine all the reasons, education is associated with lower fertility and mortality. A formal education may act as a catalyst for changes in values and behavior. Education may make people more receptive to new ideas, such as family planning. This has been reflected in a recent review, which reports that almost universally, women with a higher level of education have fewer children and that better education is associated with lower mortality (Lutz and Samir, 2011). Social scientists note that education does not have the same effect in all cultural settings and that many other factors (such as women’s status) may explain much of the association.

More educated women have higher rates of family planning use, smaller families, and healthier children than other women in the same society. Where educational levels are high, women are likely to postpone marriage until they finish their secondary schooling or college.

Married women are more likely to use family planning if they have some formal education. A 2008 Demographic and Health Survey in the Philippines indicated a contraceptive use rate of 53.2% for married women of reproductive age who had at least some secondary education. Only 18.5% of their counterparts with no formal education used a contraceptive method. The difference persists in many countries.

In most societies, total family size declines as education increases. In the mid-2000s, Honduran women aged 40–49 years

Figure 4 Population by age and sex in more-developed and less-developed countries, 2010.

with at least some secondary education had on average nearly four fewer children than women with no formal education. Similar gaps were recorded around the same time in Haiti, Nicaragua, and Guatemala and slightly less in Senegal, West Africa. Senegalese women with a secondary or higher education had 3.8 children on average, whereas women with no education had an average of 6.9 children.

Education usually expands employment options, and educated women may delay marriage and childbearing to earn income. Also, schooling may introduce young women to new ideas or values that could influence the number of children they want and also their use of family planning.

Women's education is also associated with better child health. Children of mothers with some education have fewer risk factors for infant mortality. Infants are at a higher risk of

dying if they are born to adolescents or to mothers older than 40 years, if they are born into large families, or if they are born less than 2 years after an older sibling.

By delaying marriage and childbearing, education reduces high-risk births to teenage mothers. In Colombia, for example, 55% of women aged 19 years with no formal education had a baby or were pregnant at the time of interview, whereas only 17% of those who had at least some secondary education had a baby or were pregnant. The gap was less pronounced in Bangladesh and the Philippines, as shown in [Figure 5](#), but greater in Nicaragua and Angola in the mid-2000s. Women who have completed some formal education tend to wait longer between pregnancies and births and to stop childbearing at a younger age than do less-educated women. Consequently, they have smaller families and fewer births after the age of 40 years.

In most societies, children of mothers with some education have a lower risk of dying than children of uneducated mothers. As shown in [Figure 6](#), in Cambodia, the IMR was 111 for the children of uneducated mothers, whereas it was 45 for children of women with a secondary or higher education. The twentieth century brought enormous improvements in literacy and educational levels. The recent improvements in literacy rates and educational attainments reflect the expansion of educational services throughout the world. The United Nations Educational, Scientific, and Cultural Organization (UNESCO) reported in *Education for All – Global Monitoring Report, 2011* that 83% of people aged older than 15 years were literate in a year of survey or census between 2005 and 2008 compared with only 56% in the 1950s. Basic literacy is nearly universal among populations of Europe, North America, and other industrialized regions, but the range is substantial throughout the rest of the world. In this period, an estimated 62% of the populations of South and West Asia and sub-Saharan Africa were literate, as were 72% of the populations of the Middle Eastern Arab states. More than 91% of the population are literate in Latin America and the Caribbean and about 94% in East Asia.

Rapid population growth in some countries is undermining improvements in educational attainment. For example, in the sub-Saharan African countries of Angola, Benin, and Togo, economic difficulties and burgeoning numbers of young people caused school enrollment ratios to level or decrease in the 1980s and 1990s; however, almost all countries have seen increase in the school enrollment ratios in the 2000s. In the year 1999, about 54% of girls and 62% of boys of primary school age in sub-Saharan Africa were enrolled in primary school, according to UNESCO estimates, which has increased to 74% and 78%, respectively in the year 2008. The effect of low level of school enrollment ratios will have long-term effect on the human capital of the population as measured by educational attainment of the working-age population and can only be observed in the future. [KC et al. \(2010\)](#) have shown the future based on different educational scenarios in 120 countries of the world.

Economic Development and Environment

In most societies, poor families have higher mortality and fertility than affluent families. Some of the association

Figure 5 Mother's education and teenage childbearing in selected countries, mid-2000s. *Percentage of women aged 19 years who had a child or were pregnant by the age of 19 years.

Figure 6 Mother's education and infant mortality in selected countries, mid-2000s. ^bThe infant mortality rate is the number of deaths to children less than 1 year of age per 1000 live births in a given year.

between poverty and population reflects the lower educational levels and rural residence of poor households. However, the relationship among demographic variables, poverty, and affluence is highly complex, and it is tied to the broader question of how population size and the pace of population growth are linked to economic development. The issue is further complicated by questions about whether economic growth and human activity are causing irreversible damage to the natural environment.

The research into these questions has yielded contradictory results. The extremes of these differences are characterized by two opposing camps: "pessimists" and "cornucopians". The theoretical foundation of the pessimist view can be found in writings published in 1798 by the economist Thomas Malthus. He suggested that the potential population size is limited by the amount of cropland, and therefore food, available for human consumption. Malthus assumed (based on his observations of eighteenth-century English society) that if population growth continued unchecked, population would outstrip the food available and cause widespread

famine and death. He also described a natural feedback mechanism: When the population grew too large for the available food supply, elevated mortality would reduce the population to the level that could be sustained by the amount of food produced.

A neo-Malthusian view of the relationship between population, economic growth, and resources gained credence between the 1940s and the 1960s, a period of unprecedented population growth and economic development. In a landmark study in the 1950s, Ansley Coale and Edgar Hoover found that the population growth slowed economic development and held down *per capita* incomes. These researchers also assumed that the supply of some natural resources and capital was fixed or that the supply would grow more slowly than population. Other researchers during this period expanded the idea that rapid population growth will eventually reach some absolute limit on resources and that population growth accompanied by the environmental stresses associated with economic development could cause irreversible damage to the basic natural systems that sustain life. Such concerns

were popularized by books such as “The Population Bomb” by Paul Ehrlich, “The Limits to Growth” by Dennis Meadows, and also by other authors.

The ideological basis of the “cornucopian” approach owes much to the writings of Ester Boserup in the 1960s and 1970s, who argued that the need for more food coupled with the synergy created by the concentration of intellects and flow of ideas in dense settlements can stimulate the adoption of better farming techniques or sharing of higher yield plant varieties. Economist Julian Simon, in “The Ultimate Resource” and other writings, also rejected the idea that population growth was a threat to the welfare of humans or the environment.

The scientific evidence concerning the effects of population size and growth on economic development was still inconclusive in the early 1990s at the national and regional level, but it was less ambiguous at the individual level. An extensive review of research completed in 1994 by the Overseas Development Council observed that “the clearest evidence of negative effects of population growth under high fertility is at the individual and household levels.”

In the late 1990s, several studies provided a clearer picture of the relationship between population and development at the national level and the links between poverty and demographic factors at the household level. Several studies suggested that a rapid transition from high to low fertility contributed to the economic miracles in South Korea and other East Asian countries. The rapid fertility decline increased the share of working-age people in the population relative to young and old dependents, which created a “demographic bonus.” The working-age population adds more to the economy than it consumes in services and generates taxes and savings that can be invested in education and further economic growth. This demographic bonus may last several decades; it recedes as the bulge of working-age men and women reach retirement age and the proportion of the dependent population relative to the working-age group population increases again.

Research shows that countries can benefit from this bonus only if they increase the value of their human capital – especially the youth entering the labor force – through education, and if governments adopt policies favoring international trade and industrialization. The newly industrializing Asian countries capitalized on their demographic bonus by making these investments. As researcher Andrew Mason noted, these Asian countries “raised millions of people from abject poverty and transformed some of the poorest economies in the world to some of the richest.” Research on the relationship between population change, economic development, and environmental systems remains much less clear, plagued by the complexity of the relationships and the difficulty of measuring such factors as environmental quality. At a symposium on population change and economic development in 1998, scientists assigned highest priority to research on population– development–environment linkages.

Population Prospects: 2010–2050

In the last century, the world’s population has undergone a sweeping change in both its total numbers and its distribution

across regions. The twenty-first century is likely to see the second phase of this transformation – lower fertility and an even more dramatic redistribution of population among the more-developed and less-developed countries. Nearly all future world population growth will take place in less-developed countries. In other words, the Earth is reinventing itself demographically.

Because mortality is relatively low, fertility levels and trends will determine future population size. A common issue (and a common assumption) is when, or whether, a country will reach the “magic” replacement-level TFR of about 2.1 children per woman. With fertility at replacement level, a population eventually will cease growing and “stabilize” at a given size.

Every 2 years, the UN Population Division produces a set of population projections for every country. By 2050, the UN suggests that the total world population will increase to between 8.1 and 10.6 billion. In the high- and medium-projection series, world population will still be increasing in 2050; under the low-projection series, it will have begun a gradual decline. All the three projections assume continuing declines in fertility. They differ in terms of fertility levels attained in 2050, from 1.71 for the low projection to 2.64 for the high, illustrating the major differences in total population size that can result from seemingly very small differences in childbearing during the next 40 years.

Regardless of the projection used, the UN indicates that at least 1.1 billion people will be added to the world’s population during the next 25 years. There are three reasons for this inevitable growth. First, fertility in less-developed countries is on average 60% higher than in the more-developed countries. Second, the young age structure of less-developed countries constitutes momentum for population growth for several decades, no matter what future fertility trends may be. Third, continuing improvements in mortality will contribute to additional growth, particularly in countries in which life expectancy remains comparatively low.

Recently, in addition to the projection of population by age and sex, efforts were made at the International Institute for Applied Systems Analysis on the reconstruction and projection of the population by age, sex, and educational attainment in many countries of the world for the period of 1970–2050 (Lutz *et al.*, 2007 and Samir *et al.*, 2010). The projections show that everything remaining the same and applying different education scenarios in the future, population in the year 2050 will be between 8.8 and 9.9 billion (review in Lutz and Samir, 2011).

Responses to Human Population Growth

Anxiety about the negative effects of rapid population growth and excessive population numbers has a long history. Long before Malthus, ancient Greeks and Egyptians had voiced concern about “overpopulation” in lean times. They also promoted population growth in times of plenty.

In the 1930s and 1940s, scientists and intellectuals in some less-developed countries, such as Egypt, India, and Mexico, began to express concern that rapid population growth would hinder development in their countries. Widely publicized

food shortages and famines in certain less-developed areas in the 1960s were also linked to rapid population growth.

These concerns sparked many actions throughout the world directed at lowering fertility and slowing population growth. India initiated a national policy to slow population growth in 1952. The International Planned Parenthood Federation, the largest private sector organization devoted to family planning, was founded in the same year. UN involvement in population issues also increased. The first UN meeting on global population was convened in 1954, in collaboration with the International Union for the Scientific Study of Population. UN agencies, including UNICEF and the World Health Organization, incorporated reproductive health services into their missions. In 1969, the UN Fund for Population Activities became a separate entity. Beginning in the 1960s, governments of some wealthier countries, most notably the USA, supported efforts to strengthen family planning programs in less-developed countries.

Population Policies

The idea that couples should limit their family size went against cultural mores in many societies, and some governments were loathe to support a potentially unpopular policy. Many governments embraced the more acceptable idea that fertility would decrease and that population growth would slow as living standards increased through economic development. This view was expressed at the 1974 UN World Population Conference when an Indian delegate declared that "development is the best contraceptive."

During the late 1970s and 1980s, concern about the negative effects of population growth on economic development broadened. Increasing numbers of countries accepted the idea that government actions could slow population growth.

National efforts to influence population growth include incentives to have more or fewer children and disincentives for having more than a given number of children. These efforts have met with mixed success. Some argue that China's population policies initiated in the 1970s were a success from a demographic perspective. China's TFR decreased from approximately 6.0 in the 1960s to less than 2.0 in the 1990s, in part because of government policies and programs. However, China's stringent "one-child family" policy introduced in 1979 was widely criticized for violating human rights. Between 1975 and 1977, Indira Gandhi's government in India promoted male sterilization campaigns that sometimes led to coercion. Public outrage about the reported abuses contributed to the downfall of Gandhi's government and created a backlash against family planning programs in India that took years to overcome.

Women's rights activists and others have generally opposed a demographic rationale for family planning as an infringement on individual rights. They have argued that women's rights and well-being should take precedence over national interests. Many have criticized the family planning programs' lack of integration with other health services.

During the 1970s and 1980s, women throughout the world began forming small nongovernmental organizations (NGOs) to lobby for improvements in their social, economic,

and political circumstances. By the 1990s and in 2000s, women's NGOs in less-developed countries were advocating improvements in family planning programs by better informing clients about various contraceptive methods, expanding the range of methods available, and encouraging service providers to treat clients with greater respect.

By 1997, 155 countries subsidized family planning services, and 68 stated explicitly that they wanted to slow their population growth. In Africa, the world's fastest growing region, 40 countries viewed their fertility levels as too high and 36 had policies to lower fertility. A few countries, in contrast, viewed their fertility rates as too low and welcomed faster population growth. In 1997, 23 countries reported to the UN that they had explicit policies to increase birth rates. Many governments in Europe and the former Soviet Union are concerned that continued low levels of fertility will cause rapid population aging and an eventual decline in population size. Some small oil-rich countries in the Persian Gulf also want to increase, or at least maintain, current levels of population growth. They view population growth as a way to spur socioeconomic development and reduce their reliance on foreign labor.

A New Vision: The 1994 International Conference on Population and Development

In 1994, the world community redefined the world's view of population growth and the best way to address this growth. The Program of Action adopted at the International Conference on Population and Development (ICPD) in Cairo, Egypt, agreed to the need to stabilize global population growth. One hundred and eighty countries agreed to a strategy placing population within the context of sustainable development and calling for investments in human development, especially improvements in women's status, as key to stabilizing population growth. It rejected the use of demographic targets by family planning programs and it integrated family planning into a broader women's health agenda.

Participation in the meeting by NGOs was a critical factor in achieving such widespread consensus. Twelve hundred NGOs participated as delegates and observers; and for the first time, conference deliberations on global population were informed by a wide range of interests, from the grassroots to the highest levels of government. Women's groups were a driving force behind the strong emphasis on women's empowerment as part of human development. However, this focus was also driven by research from the last 30 years that linked fertility declines with reductions in infant mortality, increased use of family planning, and improvements in women's education and other aspects of women's status contributing to their empowerment.

Despite the consensus, the ICPD engendered dissent and debate. Ideological and religious tensions characterized discussions before the conference, deliberations during the conference, and follow-up after the conference. Abortion generated the most highly publicized ideological differences. There was also a debate regarding definitions of reproductive health and family and adolescent reproductive rights and responsibilities. None of the 179 nations rejected the central

premises and goals of the ICPD, despite the range of political structures, cultures, and religions they represented. This marked the first time in the history of UN conferences that no official delegation rejected the entire document.

The final ICPD document defined reproductive health to encompass a broad range of services, including family planning, prenatal and postnatal care, medical attention at birth, cancer screening, and protection from sexually transmitted diseases. It also supported access to safe abortion where it is legal, but it stated that abortion should not be used as a method of family planning.

The ICPD Program of Action specified five goals for 2015 to improve individual and family well-being and enhance women's status, including universal access to family planning and other reproductive health services; universal access to primary school education; increased access by girls and women to secondary and higher education; and reductions in infant, child, and maternal mortality. The ICPD document also called for government and private sector actions to alleviate poverty, protect the environment, encourage greater male involvement in the family, and to address the specific health and education needs of adolescents.

A unique feature of the agreement was that it called for specific financial commitments to achieve these goals. Countries agreed that less-developed countries would pay for two-thirds of the costs of reproductive health programs, including family planning, and that more-developed countries would pay for the remaining costs, estimated to be \$17 billion per year by the year 2000. The historic agreements reached at the ICPD were reaffirmed at subsequent UN conferences in the 1990s, including the World Summit for Social Development, in Copenhagen in 1995; the Fourth World Conference on Women, in Beijing in 1995; the UN Conference on Human Settlements (or Habitat II), in Ankara in 1996; and the World Food Summit, in Rome in 1996. In 2004 and 2009, meetings were organized between the United Nations Population Fund (UNFPA), governments, and development partners to assess the progress and to identify gaps and challenges. In the 2004 meeting, it was reported by many that the progress was not as expected in certain regions of the World mainly due to the underfunding, destabilization caused by warfare and civil unrest, and the ravages of HIV/AIDS epidemic (Germaine and Kidwell, 2005). However, all stakeholders reaffirmed the agreement to continue to achieve the set targets.

In addition to ICPD's declaration, Millennium Development Goals (MDGs) are an important initiative that will effect the future development of population. In 2000, 189 countries of the world came together to set eight MDGs with a target to free people from extreme poverty and multiple deprivations by year 2015. Out of the eight goals, three specific goals (reduce child mortality; improve maternal health; and combat HIV/AIDS, malaria, and other diseases) are directly related to future population development and the rest (eradicate extreme poverty and hunger, achieve universal primary, promote gender equality and empower women, ensure environmental sustainability, and develop a global partnership for development) have an indirect effect on the future development of the population. So far, some countries have shown progress toward the goals and few countries are unlikely to reach the targets by 2015.

Conclusion

Population change has been one of the most significant events of the twentieth century. Since 1900, the world population has almost quadrupled in size and average life expectancy has increased by more than two-thirds. Declines in childbearing and shifts in population distribution were more striking than at any other time in history. Along with these population changes, the world has witnessed extraordinary improvements in technology, communication, education, and agriculture. These changes have undermined the dire predictions of Thomas Malthus and his successors that population growth would lead to worldwide famine and disease. However, these predictions may come true for some areas of the world. According to the World Bank, approximately one-half of the population of sub-Saharan Africa and two-fifth of the population of South Asia lives in poverty, subsisting on less than \$1.25 a day. The HIV/AIDS pandemic threatens the health and well-being – and the very survival – of large portions of the population in many countries.

Under all likely scenarios, the twenty-first century will see continued population increases, at least during the first few decades; that was confirmed by the increases seen in the 2000s. This is because of the built-in momentum of growth associated with the very young age structures of most less-developed countries. The growth will also be fueled by childbearing levels that are still higher than replacement levels in most areas of the world. Not all countries will experience this growth, but they will all be affected by it.

At the end of the twentieth century, the world community made financial and program commitments to continue investments in family planning and other health programs, in education, and in greater social and economic opportunities, especially for women, arguing that these are key to future population stabilization.

Glossary

Density dependence Change in the birth and death rate of a population as a result of changes in population density; usually in the form of increased mortality rate and decreased fecundity as density increases.

Focal species A species that can be monitored and managed to maintain the integrity of the ecological system of which they are a part.

Information-theoretic approach A method of comparing between multiple competing models explaining a phenomenon based on the information lost (estimated distance from the truth) by each model.

Intermediate disturbance hypothesis A hypothesis claiming that some level of disturbance is necessary to maintain biodiversity.

Minimum viable population (MVP) A method for assessing the minimum size a population must be, to bring

its extinction over a given time span to below a predetermined level.

Multimodel inference A method used to assess the uncertainty in model selection by calculating likelihoods among multiple competing hypotheses (models), most commonly based on Akaike's Information Criteria (AIC).

Population viability analysis (PVA) A method of assessing the probability of extinction for a given population within a specified time span.

Stochastic processes Processes that affect the dynamics of a population through random chance alone.

Sustained yield The removal of a constant number of animals from a wild population that can be maintained through time while keeping the population at a predetermined size.

Introduction

Although the term wildlife can be expanded to include all living organisms, the science of wildlife management, as an academic program offered and taught in universities and as written in textbooks, generally refers only to vertebrates.

Five major goals of wildlife management can be recognized.

1. Maximizing harvest/yield over time.
2. Maintaining population levels to support harvest and sport hunting.
3. Preventing extinction and increasing population survival probability.
4. Maintaining and managing the integrity of ecosystems and landscapes of which wildlife populations are a part.
5. Controlling wildlife to minimize damage to human crops and assets caused by wild populations or to return the ecosystem to some predetermined state.

As a science, wildlife management relies heavily on the understanding of ecological theory and processes, but differs from the science of ecology in its research objectives. Ecological research is targeted at formulating new hypotheses and providing the data to support or reject them. Thus, the species or setting selected to perform the research is that which is best suited to test a specific ecological theory. In contrast, research in wildlife is often dictated by real needs of specific problem-species or specific environments. The management of wild populations requires four processes: assessing the problem and defining the management objectives for the target population, monitoring and analyzing the ecology of the target

population, formulating and implementing management actions based on the identified problems and ecology of the target population, and evaluating the implemented methodology. These processes can be carried out on a local or global scale (e.g., migratory waterfowl). In addition, because wildlife management is an applied science, involving what is often a national asset, public opinion strongly influences its goals. Thus, education, law enforcement, and public relations are also legitimate and appropriate aspects of wildlife management.

Harvest and the Concept of Sustained Yield

The science and profession of wildlife management have evolved over time based on perceived needs and ecological understanding. Originally, the field of wildlife management addressed only game species and harvest issues, recognizing wildlife as a crop that is a product of the land. The realizations that populations may go extinct due to overharvesting and past harvest rates affect the future performance of wild populations were the main forces driving the development of the science (Leopold, 1933). The recognition that populations can be overharvested is not new (a review of past examples of game management can be found in Aldo Leopold's book *Game Management*). As far back as biblical times, harvesting wildlife intelligently was considered important (Deuteronomy 22:6). According to Marco Polo's writings, Kublai Khan imposed hunting regulations throughout his Mongol Empire. The first refuge in the modern western world was established

by the British Parliament in 1869. However, the formulation of wildlife management as a quantitative science occurred only during the early part of twentieth century, driven mostly by the concept of “sustained yield” and its maximization (e.g., maximum sustained yield (MSY)). Leopold’s *Game Management* was a keystone to this process, as was President Roosevelt’s doctrine of conservation.

Sustained yield refers to a constant level of harvest that when applied, will allow the harvested population to stabilize at a given size. This can be achieved by removing an amount equal to the population’s rate of increase. In the absence of limiting factors, the rate of increase of a population should remain unchanged, and, therefore, absolute growth will increase with population size (more animals have more offspring). However, populations do not grow indefinitely, which suggests that at some point, the population rate of increase begins to decline as the population increases. This density-dependent response is due to a decline in the amount of resources available per individual, which causes a subsequent reduction in reproductive success and increased mortality. The classic logistic growth equation, introduced by Verhulst in 1838, describes the growth curve of such a population, depicting an S-shaped curve of population size against time (Figure 1a). The rate of increase of the population at time t is the first derivative (dN/dt) and is given by

$$\frac{dN}{dt} = r_{\max}N \left(1 - \frac{N}{K}\right) \quad (1)$$

where N is the population size at time t , $r_{\max}$ is the maximum growth rate per individual when resources are not limiting, and K is the maximum size of the population that can be

supported over time in a particular environment (K is often termed “carrying capacity”). As can be clearly seen, there are two cases when population growth is 0; when $N = 0$ and when $K = N$. Thus a sustained yield requires that the population be kept below K . Between $N = 0$ and $N = K$, growth rate initially increases with population size and then decreases (Figure 1b). Each point on this curve represents the sustained yield for a given population size, and the highest point is the MSY.

We calculate MSY by finding the maximum value of dN/dt . This can be done analytically by taking the second derivative of the equation depicting the growth curve of the population and equating it to 0. In the case of the logistic equation,

$$\frac{d(dN/dt)}{dN} = r_{\max} \left(1 - 2\frac{N}{K}\right) = 0 \quad (2)$$

This equation equals 0 when $r_{\max} = 0$ (which is meaningless) or when $2\frac{N}{K} = 1$. Rearranging the latter, we find that $N = \frac{K}{2}$; that is, the population grows the fastest when at $\frac{1}{2}K$. To find the rate of increase at that point, we simply substitute $\frac{1}{2}K$ for N in equation (1) and find that the maximum growth rate and, therefore, MSY, is $r_{\max}\frac{K}{4}$.

Note that except for the point of MSY, a given yield (growth rate) can be achieved at two different population sizes, one on either side of MSY ($\frac{K}{2}$) – the upper and lower sustained yields. Thus it appears that one may achieve the same level of sustained yield with a small population as with a large one. However, the two points differ considerably in terms of stability. The points to the right of MSY are stable because moderate overharvesting will increase the growth rate of the population, thus compensating for the excessive harvest (and vice versa). In contrast, the points to the left of MSY are unstable because overharvesting will cause a decrease in the rate of increase. As a result, the next harvest will further decrease the population and rate of increase and so on. Initially the impact may appear minor, but this “snowballing” effect can very quickly lead to the demise of the population.

Clearly, real populations do not behave deterministically nor does their density-dependent response follow that of the logistic model. Density-dependent responses may vary depending on the species and environment, skewing the dN/dt curve; the age structure of the population must be considered; the environment (carrying capacity) constantly changes; other species (predators, competitors, etc.) interact with the population; and hunters may select for specific animal traits (sex, age group, size, etc.). Thus, much of the research on harvested populations has been directed at developing more sophisticated models with better predictive capabilities and estimating the parameters needed for them (Getz and Haight, 1989; Saether, 2001).

Although many advances have been made in this field, to date, harvest strategies in many places around the world are still implemented on a trial-and-error basis trying to just maintain a level that will support hunting and produce revenue. However, even under such protocol, harvest theory has made an important contribution in demonstrating that uncontrolled harvest can very quickly lead to the demise of populations. Furthermore, while the logic of a sustained yield set somewhat above MSY is obvious, nonecological factors may have a strong influence on harvest policy. In many

Figure 1 The logistic population growth curve as a function of time (a) and sustained yield as a function of population size (b).

species, the long-term monetary income from a sustained yield may be less than the yield offered by the economic market on regular investments (Clark, 1976). In other words, economically, a greater profit can be realized by selling licenses to hunt the entire population and investing the profits than by limiting the number of licenses to a sustained yield that will ensure the continued existence of the population. Thus, in recent years considerable effort has been directed at assessing the economic value of wildlife for nonconsumptive uses such as tourism and conservation (Fennell, 2008).

Endangered Species and Reducing the Risk of Extinction

With the biodiversity crisis coming into focus during the second half of the twentieth century, the science of conservation began to evolve. Initially, conservation to preserve an endangered species and wildlife management were treated as separate sciences. Eventually, the sciences merged in the area where they overlap (wildlife), and managing wildlife populations for conservation became an integral part of wildlife management. Topics such as management for recovery and sustainability, the dynamics of small population (especially as impacted by demographic, genetic, and stochastic environmental processes), fragmentation, and the importance of populations to the integrity of the ecosystem and biodiversity became a central focus of wildlife management. In terms of management for conservation, Caughley and Gunn (1996) recognized two central paradigms: the small population paradigm and the declining population paradigm.

The sensitivity of small wildlife populations to extinction was first recognized and expressed in 1938 in a book written by the famous American ecologist Allee. In his book (Allee, 1938), Allee writes: "The general conclusion seems to be that different species have different minimum populations below which the species cannot go with safety, and that in some instances this is considerably above the theoretical minimum of one pair." Four types of stochastic processes (Shaffer, 1981) play an important role in the dynamics of small populations and contribute to their increased risk of extinction: demographic stochasticity, genetic stochasticity (including loss of genetic variance and inbreeding depression), environmental stochasticity, and catastrophes.

The accelerated loss and fragmentation of wildlife habitat during the second half of the twentieth century restricted many wildlife populations and required that management steps be taken to minimize these stochastic effects. The size of refuges and other areas set aside for conserving wild populations must be large enough to support a population equal to or larger than the minimum viable population (MVP) (Belovsky, 1987). Corridors connecting small populations are currently considered important (Bennett, 1999), but their effectiveness has not yet been fully demonstrated. Where the establishment of corridors is not feasible, translocation has been implemented. For instance, in South Africa, mountain zebras are translocated by airlift between isolated populations. Habitat improvement and resource supply during limiting periods of harsh environmental conditions are also being used

to minimize population declines and reduce the impact of stochastic processes and risk of extinction.

The management of declining species requires that the cause of decline be identified and managed directly or indirectly. Human-related decline of wildlife populations in the twentieth century can be attributed to three main factors: overharvesting, loss and fragmentation of habitat, and the introduction of alien species. With the improved control of harvest by science and legislation, loss of habitat and fragmentation became the major causes of wildlife population declines. This process has highlighted the importance of considering space in wildlife management. Management efforts have been concentrated on land allocation for conserving wildlife and securing refuges and linkages (corridors) between patches (fragments) of adequate habitat. Roads and fencing are some of the major causes of fragmentation, and special overpasses, underpasses, and gates have been developed to ensure wildlife movement.

Managing Wildlife for Conserving the Integrity of Ecosystems and Landscapes

Wildlife populations are important for maintaining biodiversity in the system of which they are a part. Many wild populations are critical for the functioning of the entire community. Beavers (*Castor canadensis*) are a classic example of how a single species engineers change in the ecosystem beneficial to many other species. Prairie dogs (*Cynomys* spp.) are another example. Thus, in many instances, populations are managed in order to sustain species richness of the ecosystem of which they are a part. For example, research has shown that both overgrazing and undergrazing will reduce plant species richness. This is known as the intermediate disturbance hypothesis (Connell, 1978). In certain cases, herbivore populations are managed to maintain the diversity of the plant community. Elk (*Cervus elaphus*) populations were regularly controlled to maintain the existing landscape in Yellowstone National Park. Wolves (*Canis lupus*) were reintroduced (Fritts and Carbyn, 1995) into Yellowstone with the hope that they would control the elk population thus restoring cottonwood stands along the river-banks. The control, however, was not manifested by direct predation, but rather by changes in the behavior of elk that avoided the riverbanks due to the increased risk imposed by the newly present wolves (Ripple and Beschta, 2004).

The use of focal species as a tool to manage ecosystems gained popularity in the 1990s but has waned in the past decade. The underlying assumption is that by managing the focal species, the entire system, or a significant part of it, can be secured. Indicator, keystone, and umbrella species are the main types that have been suggested as focal species through which systems can be monitored, conserved, or managed.

Indicator species are species that testify to the well-being (health) of the entire ecosystem. These species are the first to respond to deterioration of the ecosystem, since they are more sensitive. By monitoring and managing the indicator species population only we can estimate and protect the welfare of the entire ecosystem. We assume that as long as the status of the

indicator species is satisfactory, the entire system is operating adequately.

Keystone species are species that play an important role in the ecosystem. These may be animals that hold most of the biomass in the ecosystem or that influence many of the other species or functions of the ecosystem. In this way, if the population of a keystone species is removed from the ecosystem, the ecosystem changes dramatically. Therefore, by managing only the population of keystone species, we are managing most of the ecosystem. In recent years, species that modify the environment (termed “ecosystem engineers”) have become a point of interest (VanNimwegen *et al.*, 2008).

Umbrella species are species that require a large area containing many types of habitats to sustain a viable population. Often these are large-bodied homeotherms with large home ranges. By securing a tract of land that is large enough to sustain a viable population of these species, many others will come under the same protection. The focus here is on leaving enough area for the umbrella species and other members of the ecosystem, but there are no direct management implications for this approach.

Control of Wildlife

The everexpanding human population ensures that human-wildlife conflicts will continue. Most of these conflicts are within the realm of damage to crops, equipment, and other assets. Thus, a major component of wildlife management is wildlife control. A good example is managing habitats around airports to reduce gull activity near runways that endangers aircraft during takeoff. Often, damage caused by wildlife is a result of human manipulation of the environment, such as outbreaks of herbivores following the eradication of predators and high concentration of canids around human waste sites leading to outbreak of rabies. Wildlife management strives to implement control measures in a manner enabling the other goals of wildlife management (sustained yield or maintaining biodiversity) to be met.

The four processes necessary for wildlife management generally apply to wildlife damage control, with some differences. These processes are the following: (1) Defining the problem. The species causing the damage must be identified, the type of damage determined, and extent of the damage evaluated. (2) Knowledge of the general ecology, behavior, and dynamics of the species causing the damage must be obtained and evaluated with special regard to its response to various control techniques. (3) The combination of (1) and (2) defines the methods that are feasible and economical to control the damage. (4) The methodology used must be evaluated. Unless the cost of control is less than the losses due to the damage, management should not be implemented.

Wildlife Management Techniques

Because wildlife management is an applied science, methods and techniques for both research and implementation are important. As a result, a considerable amount of research has been directed at developing, assessing, and improving

techniques. Techniques for managing wildlife are aimed at studying, reducing, increasing, or maintaining the population at its current level while securing its integrity (i.e., preventing loss of genetic diversity, enhancing long-term survival, preventing epizootics, etc.) and the integrity of its ecosystem. The techniques can be classified generally into two categories.

1. Applied techniques for manipulating populations by impacting survival, reproductive success, or distribution.
2. Techniques for studying, analyzing, and assessing population.

Many of the more common techniques are published in a series of *Wildlife Techniques Manuals* published by The Wildlife Society. The first of this series, edited by Mosby, was published in 1960. The most recent issue (the 6th edn.) was published in 2005 and edited by Braun. The manual covers five main topics: teaching and communication skills, study design and analytical techniques, investigational techniques, managing populations, and habitat management.

Applied Techniques for Managing Wildlife

Applied techniques may be resource (habitat) manipulation, mechanical, behavioral, immunization and immunocontraception, biological, and direct population control.

Habitat and community manipulation: This refers to managing target species by impacting important resources and other species that interact with them (i.e., habitat manipulation, or impacting predator-prey relationships and competing species, and species that are ecosystem engineers). By controlling key elements that affect the species abundance (water, shelter, predators, etc.), it is possible to manipulate its density and distribution. The increase in computer power enabled the use of spatially explicit models and Geographic Information Systems techniques to project the impacts of various habitat manipulations (Verner *et al.*, 1986).

Mechanical: The simplest and most successful method of controlling wildlife damage is exclusion by fencing. The advantages of fencing are that it is relatively fail-proof and nonlethal. However, it is expensive and labor intensive, demanding constant upkeep. Furthermore, fencing large tracts of land is a major cause of fragmentation.

Behavioral: These are modern forms of scarecrows that operate on the animal's senses and are, therefore, acoustic, olfactory, or visual. A good example of visual repellents, other than the classic scarecrow, is the silhouettes of birds of prey that are placed on large glass windows to prevent other birds from slamming into them. Examples of acoustic deterrents are gas cannons that produce explosions at irregular time lapses or recordings of alarm calls of other animals. Ultrasonic deterrents work by using sounds at a high decibel level (above 120 dB), outside the range of human hearing, to cause a painful stimulus to animals with sensitive hearing, such as canids. Olfactory repellents are chemical compounds. Two types of chemical compounds can repel animals: (1) compounds that link a food source with an induced sickness through a behavioral process called conditioned taste aversion; and (2) compounds that repel through the unpleasant stimuli of the nervous system. The first type are properly

referred to as aversive agents, while the second type are true sensory repellents.

Immunization and immunocontraception: These techniques require the administration of a vaccine either directly, by capturing and injecting, or indirectly, by oral administration with bait. A major advancement in wildlife management in the past decade is the control of rabies by oral immunization. Immunocontraception is a very attractive method of control because it is potentially highly species specific, but it so far has had limited success.

Biological: Biological control has been mostly effective against insects. There are only a few cases in which biological control was effectively applied to wildlife. Of these, the introduction of *Myxoma* virus to control rabbits introduced into Australia is the most famous. Although complete eradication was not achieved, the virus now holds the rabbit population at 20% of its original size.

Direct population control: Direct population control refers to the removal (harvesting) or addition (reintroduction and translocation) of animals. Removal is usually used when the animal is a game species and can also be controlled by hunting license quotas. Its main advantages are that it is species specific, the number of animals removed can be closely controlled, and it has limited impact on the environment. Reintroductions and translocations are important methods for enhancing the viability of existing populations and reducing the species risk of extinction.

Studying, Analyzing, and Population-Assessing Techniques

A major prerequisite of sound management is the accurate estimates of population size and dynamics, and determination of how these are influenced by other factors. Consequently, a significant part of wildlife science today is directed at the development and improvement of estimation techniques for assessing population density, survival, reproduction success, occupancy, well-being, age structure, density-dependent responses, and interspecific interactions. Such data are the basic requirements for estimating sustainable harvest quotas in different and variable environments and assessing extinction probability and other risks.

Rigorous statistical methods for assessing density and survival based on maximum likelihood estimation techniques, are continuously being refined. These methods evolved from a landmark paper (Seber, 1970) on estimating survival from the recovery of dead animals, and the insight of David R. Anderson of the US Fish and Wildlife Service who recognized the potential of Seber's work. Computer software such as DISTANCE, SURVIV, ESTIMATE, JOLLY, BROWNIE, and more recently MARK, were developed specifically for wildlife research and management (Dinsmore and Johnson, 2005).

Research and management of wildlife are carried out over large geographic areas, often with limited access and visibility. Considerable effort has been directed toward developing remote data collection techniques using indirect methods of assessing population condition and nutrition by using individual animal physiological indicators (Servello *et al.*, 2005).

Methods for assessing the viability of small populations (population and habitat viability analysis, (PHVA)) and

estimating the minimum population size necessary to ensure its long-term existence (MVP) have been developed based on stochastic theory (Burgman *et al.*, 1993). Commercial software such as RAMAS and Vortex are available for PHVA and MVP analysis; however, in most cases and due to the detailed knowledge required, the data are insufficient for a reliable analysis.

Clearly the greatest change in the analysis of data from wild populations in the past decade is the use of the Kullback-Leibler information-theoretic approach and multimodel inference (as opposed to the standard Popperian approach). This approach was integrated into the field of wildlife management and evolved within it, driven by the need to deal with multiple potential predictor variables (Burnham and Anderson, 2002). The approach has consequently filtered into the basic-ecology literature and reflects a paradigm shift in this and related fields.

Glossary

Booklungs One to four pairs of abdominal respiratory organs consisting of a thin, multifolded membrane (the book's "pages") over which blood circulates and that is open to an air-filled cavity on the outside, itself open to the exterior via a spiracle. Gases passively diffuse back and forth across the membrane.

Chelicerae (chelate) The first pair of preoral appendages. They are at most three segmented, usually two, and usually the distal segment acts against the penultimate to grab or hold prey or objects. If the basal segment has a finger-shaped outgrowth against which the distal segment operates, the chelicerae are chelate (as in scorpions or harvestmen). If not, the chelicerae are subchelate, as in spiders and tailless whip scorpions. In parasitic mites the chelicerae are modified into piercing stylets.

Monophyly A true, historical, evolutionary lineage consisting of an ancestor and all of its descendants; defined by shared, derived characters.

Ovoviviparous Young are born alive, but the mother simply retains eggs within her body until they hatch.

Paraphyly A group consisting of an ancestor and only some of its descendants. Defined by primitive characters.

Pedipalps The second pair of preoral appendages. They are multisegmented and primitively leg-like. They may be raptorial or sensory (like antennae) or used as walking legs.

Phoresy A method of long-range dispersal in which the dispersing animal attaches itself to another animal (e.g., beetle, wasp, or bird) that carries the disperser along with it until the disperser drops off or disembarks.

Polyphyly A group in which the most recent common ancestor of the included taxa is excluded from the group. Defined by convergent, nonhomologous characters.

Spermatophore A chitinous container produced by the male to hold sperm. It may be attached to the substrate for the female to find or passed to the female from the male during mating.

Spinnerets Usually three, rarely four pairs of modified terminal abdominal appendages in spiders bearing one to hundreds of hollow spigots from which silk is drawn.

Tracheae A system of hollow, branched or unbranched air-conducting tubes used for respiration, opening via abdominal spiracles. They may or may not extend into the cephalothorax or legs.

Trichobothria Long, delicate, slender setae set in broad, shallow innervated sockets in the cuticle. Trichobothria are sensitive to vibration or near-field air movement and are a major sense organ of arachnids.

Overview of Arachnida

The known diversity of arachnids is approximately 640 families, 9000 genera, and 93,000 species (Table 1), but there

are many thousands of new mite and spider species still undescribed and hundreds to thousands of undescribed species in the remaining orders. Together with the marine horseshoe crabs (Xiphosura) and sea spiders (Pycnogonida), arachnids

Table 1

Latin name ^a	Common name	No. of Families	No. of Genera	No. of Described species
Arachnida	Arachnids	648	9241	±92,680
Araneae	Spiders	108	3200	±37,000
Palpigradi	Micro-whip scorpions	2	6(5)	80
Uropygi	Whip scorpions	1	16	101
Amblypygi	Whip spiders, tailless whip scorpions	5	20	126
Schizomida	Schizomids	2	31	195
Solifugae	Wind spiders	12	153	1,065
Pseudoscorpiones	Pseudoscorpions	24	430	3,100
Ricinulei	Ricinuleids	1	3	53
Opiliones	Harvestman	44	1554	±4,500
Scorpiones	Scorpions	18	156	1,260
Acari	Mites, ticks	431	3672	45,200

^aModified from Adis J and Harvey MS (2000) How many Arachnida and Myriapoda are there worldwide and in Amazonia? *Stud. Neotropical Fauna Environ.* 35: 139–141, with data for the Acari from Walter DE and Proctor HC (1999) *Mites: Ecology, Evolution and Behaviour*. Wallingford: Univ. of New South Wales Press and CABI.

comprise the arthropod subphylum Chelicerata, named for the characteristic first pair of preoral appendages, the chelate, or pinching, mouthparts. In some arachnid groups the chelicerae are further modified into venomous fangs or piercing stylets to suck body or plant fluids. Arachnids are the only terrestrial chelicerates. Along with the insects, arachnids are by far the most species-rich, abundant, and widely distributed terrestrial arthropods. Acarologists (scientists who study mites and ticks) estimate that there may be as many mite species as beetles, implying that total extant arachnid diversity may exceed 1 million species. Arachnids are an important component of every terrestrial ecosystem, but, apart from several specialized mite lineages, none are aquatic or marine. Although most arachnids share many ancestral similarities in body plan and lifestyle, many extremely specialized groups exist, especially among the mites (Acari).

Although arachnids are commonly mistaken for some sort of peculiar insect, the groups are quite distinct and only distantly related. Arachnids have four pairs of walking legs rather than three (except the young stages of mites and the related Ricinulei), only two (not three) major body parts, and simpler chelate mouth-parts rather than the more complex feeding apparatus of insects. The anterior body part is specialized for locomotion and the posterior for digestion and reproduction. Arachnids lack the wings, antennae, and compound eyes usual in insects. In many groups the first pair of walking legs (e.g., amblypygids, uropygids, schizomids, solifuges, palpigrades, and many mites) are elongate and function in much the same way as insect antennae. **Figure 1** depicts a consensus view of the position of arachnids in the arthropod evolutionary tree.

Arachnids and hexapods (which insects dominate) differ in fundamental ways, possibly because their marine ancestors were already distinct lineages in the Silurian and both colonized land independently. They therefore solved the fundamental challenges of terrestrial existence (support, breathing, water balance, reproduction in dry environments, and nitrogenous waste management) in different ways. The arachnid skeleton is hydraulic; arachnids, except scorpions and pseudoscorpions, lack extensor muscles at key joints. Instead, the animal pumps blood into the limb to extend it. The basic arachnid uses two (or four) pairs of book lungs (gas-permeable, gill-like membranes with blood on one side and open to the air on the other) to exchange carbon dioxide for oxygen

Figure 1 Phylogenetic position of Arachnida among arthropods.

rather than tracheae. Many arachnids possess rudimentary tracheal systems that supplement or replace book lungs, but ventilation is passive, not active. Unlike insect tracheae, arachnid tracheae generally do not ramify throughout the entire body or penetrate inside body cells. For all these reasons, insect tracheae more efficiently deliver oxygen directly to tissue, and insects in general can lead more energy-intensive lifestyles than arachnids. Arachnids have significantly lower metabolic rates than other terrestrial arthropods, especially insects. Whereas male insects transfer sperm directly to the female using an intromittent organ, in most arachnids males either ejaculate onto a special structure and carry the sperm mass with a specialized appendage until the female is encountered or they deposit the sperm mass in a specially built receptacle (spermatophore) fixed to the substrate, which the female picks up. Major exceptions include the harvestmen, astigmatic mites, and spider mites, which transfer sperm to the female by means of an intromittent organ, and the water mites (Prostigmata: Hydracarina), which transfer sperm directly by opposing the male gonopore to the female gonopore.

Arachnids are peculiar among animals in using guanine (three nitrogen atoms per molecule) as well as the much more common uric acid (two nitrogen atoms per molecule) to eliminate nitrogenous wastes. Insects have compound eyes, which provide relatively excellent vision. Arachnids lost compound eyes early in their evolutionary history but retain usually one to five (commonly four) pairs of simple eyes, much inferior in acuity to compound eyes. Schizomids, palpigrades, ricinuleids, mites, and other mainly litter-dwelling arachnid groups are nearly always blind. Vision is much less important to arachnids than vibration. Many structures (slit sense organs, trichobothria, and lyriform organs) are specialized to detect minute vibrations and slight air currents.

Arachnids are also peculiar in that species of most arachnid groups digest food externally. They have a strong pumping stomach that rhythmically vomits and sucks digestive juice through a preoral cavity formed by the basal articles of the pedipalps back and forth over their prey. The process continues until only the hard, indigestible parts of the prey remain. Only liquids or very small particles are actually ingested. Some major groups of arachnids have internal digestion, however. Opiliones and several groups of mites are particulate feeders, and parasitism of plants, vertebrates, and invertebrates has arisen repeatedly in the mites. External digestion is a major obstacle to life in fresh water or the sea. Arachnids are also notable for their ability to withstand starvation. Fasts of weeks or even months are routine for larger arachnids. Some scorpions and mygalomorph spiders live for more than 1 year without food, and adult soft ticks (Argasidae) can survive for years without feeding.

Reproduction and Growth

Like all arthropods, arachnids grow by molting their exoskeletons and expanding the larger skin beneath with blood pressure before it hardens into the usual tough covering. The number of molts to maturity varies widely between 3 and 10–12; five is perhaps the most common. Life spans also vary greatly. The majority of mites and spiders live less than 1 year,

but several years is common among the larger forms, and mygalomorph spiders can live 20–30 years in captivity. Some arachnids cease molting at adulthood but others continue to molt periodically until death.

The ancestral reproductive pattern of sperm transfer is via spermatophore, modified in spiders, harvestmen, mites, and ricinuleids. Except among permanently social species and many mites, the sex ratio is equal, and parthenogenesis is rare. In the vast majority of species, males and females meet only to mate; cohabitation and parental care are uncommon. Nevertheless, various spiders, scorpions, schizomids, uropygids, and amblypygids may carry and feed their young, and in some harvestmen the male cares for the eggs in a specially built nest. Pseudoscorpion females nourish eggs with secretions from their bodies, and scorpions bear only live young. Females commonly guard their eggs until they hatch, but the young are usually abandoned soon thereafter. Mites are more diverse in reproductive strategies than nonacarine arachnids.

Ecology

Despite huge numbers of species (Table 1), arachnid biology is coherent in many ways (even though exceptions to nearly every generalization exist). Most arachnid orders consist of fluid-feeding predators, and predation still dominates these groups today. However, opilionids and two of the three orders of mites are particulate-feeders on detritus, fungi, and small invertebrates. Additionally, parasitism of vertebrates, invertebrates, and plants has arisen numerous times within the Acari and radiations within these lineages account for most of the 45,000 described species of mites.

Non-acarine arachnids tend to be at the top of the terrestrial invertebrate food chain wherever they occur. At one site in Israel, mites comprised 35% of the total soil arthropod population; in the Amazon ranges from 35 to 55% have been reported. Some harvestmen eat dead or decaying animal or plant material. Arachnids are generally nocturnal, despite numbers of diurnal harvestmen, spiders, and mites. Nocturnal forms hide in dark crevices and burrows during the day; several orders are morphologically specialized to inhabit small spaces. With the exception of the wind spiders (Solifugae), arachnids tend to be torpid and sedentary—none fly, for example, nor do any move constantly like ants or other active insects. The basic arachnid forages with a “sit and wait,” solitary strategy. They move rarely and wait for prey to encounter them. Prey is then seized with a quick strike and immobilized. Highly organized social systems are known only in a few spiders, but loose aggregations (spiders, harvestmen, and pseudoscorpions) are not uncommon, usually in response to high prey density or limited refugia. Most arachnids are well adapted to last for long periods (weeks or months) without food; in the laboratory some have survived for more than 1 year. Only jumping spiders among arachnids have notably good vision; otherwise, they orient primarily via vibrations and touch.

Arachnids occupy all terrestrial habitats—deserts, forests, tundra, grasslands, mountaintops, soils, litter, caves, etc. Hydrachnid mites (approximately 5000 species) are important components of most freshwater ecosystems; other

mites are parasites of marine organisms, whereas others inhabit marine sediments, including the deepest oceanic trenches. Otherwise, arachnids are exclusively terrestrial. A few groups, such as scorpions and wind spiders, conserve body water as well as any arthropod and thus tend to dominate in deserts. The majority need moist conditions to survive. Schizomids, paligrades, and ricinuleids are apparently restricted to the interstices of moist tropical and subtropical leaf litter or equally constant and moist habitats.

Phylogeny and Taxonomy

The most commonly encountered arachnids are spiders, scorpions, harvestmen, and mites, but the class contains seven smaller groups of terrestrial arthropods less familiar to the general public (Figure 1). The largest and heaviest arachnid is the African scorpion *Pandinus imperator*, which may reach a length of 18–20 cm. The smallest are perhaps the gall mites at 80 μm . No group of arachnids is well-known by vertebrate, butterfly, or vascular plant standards. Popular manuals are available for only a smattering of the most common species of spiders in Europe, North America, and Japan; all others require technical literature and specialist knowledge to identify. Myriad species are undescribed and undiscovered; at best, the approximately 93,000 known arachnid species are but one-third of the probable total, and probably much less. Most undescribed arachnid species are mites.

The study of arachnids is called arachnology. The principal international scientific society for nonacarines has approximately 600 members but many more belong only to regional societies. The taxonomy of arachnids is still a monumental task and an obstacle to better ecological and biotechnological understanding of arachnids, but the number of arachnid taxonomists is small and decreasing, and new students are not being trained. There are no comprehensive arachnology texts appropriate for university teaching (three exist for Acari), although modern “biologies” are available for spiders, scorpions, solifuges, pseudoscorpions, and various aspects of mite biology.

Paleontology

Arachnida were among the earliest terrestrial animals. The marked similarity between fossil and recent forms in overall body plan and morphology suggests few changes over hundreds of millions of years. The earliest sites for terrestrial arachnids are Early Devonian (400 Ma) and Late Silurian (414 Ma); the extinct arachnid order Trigonotarbi figures prominently, but mites are also present. The fossil record of all arachnids is comparatively poorly known. The 13 living and extinct orders are still known from less than 50 major time horizons since the Silurian; gaps remain more common than fossils. Arachnids seem to have invaded land in the Silurian and reached a pinnacle of ordinal diversity by the Carboniferous. The latest dates for the extinct orders Trigonotarbi and Phalangiotarbi are Permian and Carboniferous, respectively. No order seems to have succumbed to the end Cretaceous event that eliminated the dinosaurs. The earliest arachnid fossils are aquatic scorpions from the Late Silurian.

Spiders, pseudoscorpions, terrestrial scorpions, and mites are known from the Devonian. The scorpion-like Eurypterida, which are sister to true Arachnida, also may have become extinct at the Permo–Triassic boundary; the youngest fossils are also Carboniferous. The phylogeny in **Figure 2** implies that many arachnid clades must predate all scorpion fossils; an alternate opinion, based on less evidence, is that scorpions instead are sister to eurypterids, and that the phylogeny of **Figure 2** will be shown to be incorrect. Small size may explain the rarity of schizomid and palpigrade fossils, but mites in the Devonian show that small arachnid fossils can persist. Given the sparse record, it may well be that all arachnid orders were distinct and essentially modern in appearance by end Silurian–Early Devonian times. The most detailed arachnid fossils are “inclusions” in amber, which is fossilized gum or tree sap. The organisms became caught in the wet sap and were fossilized along with the sap. Cenozoic amber arachnid fossils 40–80 million years old can mostly be placed in modern genera; in some cases, the fossils are difficult or impossible to distinguish from modern species. Ecological relations are also preserved: Parasitic mites occur on their insect hosts, for example, thus documenting the antiquity and diversity of mite parasitism.

Araneae

Araneae is the second largest arachnid order with 108 families, 3200 genera, and approximately 37,000 species described (second to mites). Spiders are distinguished from other arachnids by their silk-producing spinnerets at the end of the abdomen and the prosomal poison glands exiting through their chelicerae modified as fangs (**Figure 3**). Spiders are among the very few animals that use silk throughout their entire lives. A narrow stalk joins the abdomen to the prosoma, allowing great flexibility and precise orientation of the

abdominal spinnerets. Pedipalps are leg-like and short. Colors are predominantly dull tans, browns, and blacks, but spiders are occasionally very colorful, even iridescent. The abdomen of most spiders shows no trace of ancestral segmentation, unlike that of other arachnids. The Neotropical tarantula *Theraphosa leblondi* (Theraphosidae) is the largest spider at about 10 cm in body length. The smallest spiders are the tiny orb-weaving Symphytognathidae; adults are less than 1mm long.

Ecology

Spiders are very abundant. One calculation estimated 5 million animals per hectare in an English meadow. Another found 29,000 per cubic meter in an English sewage treatment plant. These are extreme values, but “average” nondesert habitat probably supports at least 1 and as many as 800 spiders per square meter. Many spider species disperse by ballooning. Ballooning spiders spin a silk line until it is caught by the wind and lifted aloft—potentially for hundreds or thousands of kilometers. One study estimated that 216,000 spiders per hectare may balloon into tilled fields during the growing season. Point diversities per hectare may vary from 100 species in moderate temperate zones to 600 or more in the wet tropics. Boreal diversities are less, perhaps 20–50 species per hectare.

Spiders are the only animals to use silk throughout their lives. Silk is one of the strongest and toughest natural fibers known and compares favorably with the best man-made filaments. Eight different kinds of spider silk have been discovered, but the maximum made by any single species is seven. Orb web spinners, for example, make two varieties of stiff, tough silk for weight-bearing structural fibers and safety lines, cement to fix silk to itself and substrate, sticky silk or glue to capture prey, rubbery silk to carry the sticky silk in the web, specialized silk for eggsacs, and thin, weak silk spun as multiple fibers to wrap prey, cradle eggs, and for other general purposes. All spiders are capable of spinning silk as soon as they leave the eggsac, and all make at least safety lines (“draglines”) and the cement to attach them to substrate. Approximately half of spider species spin webs to capture prey. Web architectures are taxonomically specific and provide

Figure 2 Phylogeny of arachnid orders.

Figure 3 Spider (Araneae: Ctenidae, *Cupiennius* sp.).

many clues for reconstructing spider evolution. The remaining spiders are ambush predators such as the crab spiders, which lurk inside flowers to attack pollinators, tube or retreat dwellers that forage in the very limited area at the burrow mouth, or vagabond predators such as wolf, ground, or jumping spiders.

Reproduction and Growth

Reproduction in spiders requires the male to ejaculate sperm onto a specially constructed sperm web. He then sucks up the sperm into specialized sperm transfer organs at the pedipalpal tips. Only adult males have such structures; their form is usually species-specific. With his palps filled, the male then searches for females. Females are usually more sedentary than males. Life is short for adult males, both because of predation and because they eat little as adults. The duration of courtship and copulation varies from seconds to days, but it ends with the insertion of the male pedipalp and transfer of sperm into the female gonopore. Females store the sperm and sometime later construct a silken eggsac into which 1–2500 eggs are placed. Eggs are fertilized only as they exit the female's body. Parental care is rare and highly variable, ranging from simple guarding of eggsac to actively feeding the babies. In at least one crab spider the female dies as the juveniles emerge from the eggsac, which then eat their mother's body. About 20 species of spiders are extremely social. Males are rare (1:40–100), generations overlap, food is shared, and prey capture and brood care are cooperative. Colony sizes range from a dozen to several thousand individuals.

Phylogeny and Taxonomy

Spiders are the seventh largest zoological order on Earth (after Coleoptera, Hymenoptera, Lepidoptera, Diptera, Hemiptera, and Acari), and of these they are the only one for which all taxonomic literature is fully cataloged. Catalogs greatly facilitate all kinds of research because scientists can easily determine the current taxonomic status and history of any described species and thus decide whether a given specimen belongs to a described species or not. At higher taxonomic levels (approximately, family) a basic, first-draft phylogeny is nearly complete. At the species level the easiest species-specific characters are found in the male and female genitalia. Species boundaries in spiders are generally clear-cut. However, the species taxonomy of spiders is based overwhelmingly on morphology. If more costly and sophisticated molecular methods were routinely applied, the number of distinguishable spider "taxa" would certainly increase.

The fundamental phylogenetic division in spiders is between the primitive mesotheles (spinnerets towards the middle of the abdomen) and the opisthotheles (spinnerets terminal). Within opisthotheles there are again two basic groups, the mygalomorphs (tarantulas and their allies) and araneomorphs (so-called "true" spiders). Mesotheles and mygalomorphs are not particularly diverse at the species level; araneomorphs currently include 94% of all known spider species and this disparity will certainly increase. Within

araneomorphs the basal taxa are a few relictually distributed families in north and south temperate regions. Araneomorph haplogynes are diverse, but again comprise relatively few species. The araneomorph Entelegynae includes the bulk of modern spiders. Seven spider families currently contain more than 1000 species—all are entelegyne.

During a recent 39-year period, an average of 314 new species were described per year (12,200 total), but an annual average of 104 old names were synonymized, for a net gain of approximately 200 species per year (8800 total). Estimates of total spider diversity range from 76 to 170,000. Lower estimates mostly extrapolate from the proportions of new versus known species in taxonomic publications or are based on comparisons to well-known groups. The higher estimates take into account that many regions, particularly those richest in spider species, are disproportionately undercollected. In any case, the real diversity of spiders will never be known because a potentially great fraction will certainly go extinct before being discovered, much less described.

Major Lineages

Mesothelae

Liphistiidae is the only extant family and is limited to areas of Southeast Asia and Japan. Only a few dozen species are known, but some are common where they occur. Liphistiids retain many primitive morphological features, such as eight (rather than six or fewer) segmented spinnerets that insert anteriorly rather than terminally on the semi-segmented abdomen. Their biology may likewise represent the ecological "ground plan" for spiders. Liphistiids live in silk-lined tubes equipped with rudimentary trap doors in banks and cave entrances. Sometimes, silk "trip lines" lead away from the burrow entrance to extend the sensory radius of the animal. They are nocturnal, ambush predators. They live for 5–8 years, are remarkably sedentary, and consume a catholic diet of mainly walking prey.

Mygalomorphae

Mygalomorphs include the tarantulas or baboon spiders (Theraphosidae), trap-door spiders (Ctenizidae, Actinopodidae, Migidae, etc.), purse web spiders (Atypidae), funnel web spiders (Hexathelidae), and several other families with no common name. Mygalomorphs number 15 families and approximately 2200 species, but several of the families are para- or polyphyletic. A more realistic estimate is 20–30 "family-level" groups. Like mesotheles, mygalomorphs tend to live in burrows and forage at the burrow entrance or for a very limited distance around it. Some theraphosids are arboreal and spin elaborate silken retreats. Diplurids make extensive webs but are virtually unique among mygalomorphs. The venomous Australian funnel web spiders (*Atrax* and *Hadronyche*: Hexathelidae) were responsible for many deaths until an antivenin was developed in the 1980s. The large theraphosid baboon spiders are not seriously venomous to humans, despite their popular reputation.

Araneomorphae

Araneomorphs include approximately 94% of known spider species. Even the most primitive araneomorphs are very different from mygalomorphs and mesotheles. Basal araneomorphs

tend to be much smaller, and most are obligate web spinners with elaborate spinnerets capable of making adhesive “cribellate” silk. Cribellate silk is adhesive due to the extremely fine threads drawn from the cribellum, the very modified and fused anterior pair of spinnerets. Adhesive silk makes feasible a greater variety of web architectures, and these basal araneomorphs spin elaborate catching webs. The sister group of all remaining araneomorphs is the family Hypochilidae; its dozen or so species are limited to the Appalachian Mountains, a few places in western North America, and equally restricted sites in China.

Haplogynae Haplogynae comprises 17 families of spiders of diverse habits and worldwide distribution. Filistatidae are cribellate web-spinning spiders. Their web architecture is not much different from that of the mygalomorph diplurids—a sheet that narrows to a silk-lined retreat in a tube or crevice. Diguettids make dry silk webs. The majority of haplogynes are leaf-litter specialists and are vagabond, webless predators. The venomous brown recluse spiders (*Loxosceles* spp.) are haplogyne sicariids. The sister group of *Loxosceles* in southern Africa (*Sicarius*) has also been implicated in medically serious bites.

Entelegynae The remaining 70 families of spiders are the Entelegynae. Entelegynes share many evolutionary novelties. Females have a convoluted abdominal plate protecting their gonopore, which male genitalia must navigate successfully to achieve insemination. Sperm are stored in a unique “flow-through” system so that the female reproductive tract has two apertures to the outside. Female entelegynes also make special silk used exclusively in eggsacs, although its exact role is unknown. The lateral eyes possess a canoe-shaped tapetum that in some spiders enables orientation via polarized light. Although the higher phylogeny has been worked out for many entelegyne lineages, some very large ones remain unstudied, and the relationships between entelegyne lineages are also controversial.

Lycosoidea includes 11 families of mainly hunting spiders, some with common names: lynx, wolf, fishing, or tropical wolf spiders. Lycosidae (wolf spiders) and Pisauridae (fishing spiders) are common, cosmopolitan lycosoid spiders. Lycosoids occur in all terrestrial habitats, and some are semiaquatic in their ability to run across the surface of the water or dive beneath the surface. Web spinning is rare among lycosoids; some may have regained it after evolutionary loss. Most species are vagabond predators or, occasionally, tube dwellers. Active at night, they move sporadically or wait until prey approaches and then attack with powerful front legs and chelicerae. They are built strongly and run and jump with agility. The South American ctenid *Phoneutria* is venomous to humans.

Dionycha includes 17 families of spiders with two tarsal claws and a tuft of hair rather than the more common three claws and no claw tufts. The monophyly of Dionycha is by no means certain. Dionycha are also hunting spiders and have habits similar to those of lycosoids. Crab spiders (Thomisidae) wait for insect prey in flowers. Jumping spiders (Salticidae), the largest spider family, can be very brightly colored and often prefer to jump rather than walk. Their vision is superior

to any other arachnid; salticids are the only sizable spider lineage that is strictly diurnal.

Orbiculariae includes 14 families of spiders and approximately 12,000 species. Most orbicularians spin prey-catching webs, but a few groups have secondarily lost the web-spinning habit. The primitive web architecture seems to be the orb—the classic spider web of radially symmetric, stiff, dry spokes supporting a spiral of sticky silk—but more orbicularian species have lost or modified the orb architecture than retained it. Web spiders rely exclusively on webs for prey capture. Araneidae (common orb weavers), Linyphiidae (sheet weavers), and Theridiidae (cobweb weavers) are the largest families. The venomous widow spiders (*Latrodectus*) are theridiids and are distributed worldwide; several species are spread by humans and are now cosmopolitan.

Scorpiones

About 1256 species of scorpions are currently known in 156 genera and 18 families (Figure 4). Scorpions are one of the better collected arachnid groups so that huge increases in diversity are not as likely as in mites or spiders. Estimates of total diversity run as high as 7000 species. All scorpions have large, obvious pedipalps modified as pincers, both body regions are broadly joined, the distal abdomen is narrowed into a flexible tail bearing a venomous stinger at the end, and ventrally. The abdomen bears a pair of comb-like sensory appendages

Figure 4 Scorpion (Scorpiones: Vaejovidae, *Uroctonus* sp.) (photograph by James C. Cokendolpher).

known as pectines. Colors vary from translucent to brown or black. Curiously, they fluoresce under ultraviolet light, a discovery that has galvanized recent field research on these animals. The longest is *Hadogenes troglodytes* at 21 cm, but *Pandinus imperator* is nearly as long and much heavier. The external morphology of recent scorpions is impressively similar to Silurian fossils. Formerly scorpions were thought to be the sister group of all other arachnids because they closely resemble the extinct marine eurypterids that are the sister group of all arachnids. Better analysis of morphological data (Figure 2), weakly corroborated by molecular evidence, suggests that scorpions are more deeply imbedded in the arachnid clade and merely retain many primitive features. The issue is controversial.

Scorpions are the only arachnids with a narrow post-abdomen ("tail") terminating in a venomous sting. The sting is most often used for defense, although scorpions will sting large or strong prey. The sting of most scorpions is painful—like wasp or hornet stings—but not dangerous. Characteristically, scorpions with slender pedipalps are more prone to sting their prey, whereas those with robust pedipalps tend to crush prey. The Central American genus *Centruroides*, Brazilian *Tityus*, and Old World *Androctonus*, *Leiurus*, *Mesobuthus*, and *Parabuthus* are very venomous and medically important. In Mexico, *Centruroides* spp. sting 300,000 and kill 1000 people annually; *Androctonus*, *Leiurus*, and *Mesobuthus* kill thousands annually in Egypt and Pakistan alone. Excepting ticks that spread disease, scorpions are by far the most dangerous arachnids to humans. Scorpions are correspondingly prominent in mythology and folklore (e.g., the zodiacal constellation "Scorpio"). Scorpion venoms typically contain multiple low-molecular-weight proteinaceous neurotoxins. Scorpion blood inactivates scorpion venom, but if the venom is injected directly in a nerve, the animal rapidly dies. *Parabuthus transvaalicus* and *P. villosus* squirt venom to damage corneas, like spitting cobras.

Ecology

Scorpions are most diverse in deserts or similar dry areas, although they are reliably present in moist ecosystems if the temperature is not too cold. They now occur on all major landmasses except Antarctica. Favored habitats are burrows, under bark, stones, or logs, or inside small crevices. Burrows may be as deep as 40–80 cm, serving to escape the hot daytime temperatures in deserts. Because they like hard substrates and dry conditions, scorpions adapt well to human structures. Most scorpions are ground dwelling, but many species are arboreal, especially in the neotropics. In canopy fogging at four Amazonian sites in Peru, all of approximately 100 specimens were Buthidae (J. Ochoa, personal communication). A few are limited to lightless caves.

Scorpions are almost invariably nocturnal, although the African *P. villosus* is predominantly diurnal. The eyes seem to detect luminosity at best. Prey movements are detected by tarsal sense organs at distances up to 15 cm, and prey are attacked in a single motion. At distances up

to 30 cm prey are located through orientation responses. The large, pincher-like pedipalps immobilize prey; thereafter, pieces are torn off by the chelicerae and digested in the pre-oral cavity before being sucked into the gut. Scorpions can be important consumers in some communities. In Israel, *Scorpio maurus* annually ate an average of 11% of the isopod population, which was not the only item in their diet. At moderate densities of 1.5 kg/ha, *Urodacus yaschenko*i ate an annual average of 7.9 kg/ha of prey. Cannibalism and predation by other scorpion species are thought to be the most important sources of mortality, but other top invertebrate predators (e.g., spiders) and vertebrates are also important scorpion predators. Generally, mortality is highest immediately after birth, lower for intermediate-aged animals, and high for adults (e.g., 65, 30, and 60%, respectively, per year for the Australian *Urodacus manicatus*). Scorpion mortality is particularly high among males because of their high activity levels and mobility during the breeding season. Cannibalism by females is a significant cause of male death. Biased adult sex ratios of 1.2–1.4 : 1 are typical. Communal behavior, however, does occur. For example, family groups up to 15 individuals of the Brazilian *Opis-thacanthus cayaporum* cooperate to construct and occupy communal chambers in the center of termite mounds. The African *Heterometrus* spp. also construct and share a communal burrow, inhabited by individuals of various ages. "Piles" of 20–30 individuals of *Centruroides exilicauda* are found in the winter months. Groups of 5 individuals of *Mesobuthus martensi*, all of the same age and all with their heads oriented toward a central spot, have been found under wet rocks in the intertidal zone.

The vast majority of scorpion species are subtropical or tropical. Point diversity (the number of species sympatric at one site) peaks in subtropical deserts and is particularly high (6 or 7, with a maximum of 12) in Baja California. Two to three species per site is more usual. *Vaejovis littoralis* reaches unusually high densities (8–12/m²) in the drift line along the Gulf of California. The North American *Paruroctonus boreus* occurs as far north as British Columbia and Alberta, and the European *Euscorpius germanus* reaches the southern Alps. Even tropical scorpions sometimes inhabit extreme conditions; *Orobuthiurus crassimanus* was collected at 5560 m in the Peruvian Andes.

Reproduction

Reproduction in scorpions is via a spermatophore attached to the substrate. The male completes production of the spermatophore inside his body, deposits the sperm inside, and attaches the spermatophore to the substrate, all the while holding on to the female during preliminary courtship. The spermatophore is "spring-loaded" and catapults the sperm mass into the female gonopore when a lever is touched. Scorpions are exclusively ovoviviparous or viviparous. The 1–105 young are born live and cling to the mother for the first few molts. A few species are parthenogenetic. Scorpions live 4 or 5 years (rarely 8); they do not molt as adults.

Phylogeny and Taxonomy

The higher classification of scorpions has changed dramatically as classical data have been reinterpreted phylogenetically. The old system proposed a few, huge, polyphyletic families about which nothing much in general could be said; now 16 or 18 families with increasingly coherent biologies are recognized. Species limits in scorpions are often difficult because scorpion genitalia are usually not species-specific. By tradition, scorpion taxonomists use the subspecies category more than most arachnologists. About 150 subspecies are recognized in addition to the 1260 species, but because these are easily distinguished they are probably distinct species. A classic example is the 25 non-overlapping, fully distinct subspecies of *Scorpio maurus*. Species-level taxonomic characters include the surface sculpturing of the exoskeleton, morphometric data, the number and position of pedipalpal trichobothria, and the hemispermatophores—internal male structures that produce the spermatophore.

Major Lineages

The basal division in Scorpiones is between the buthoids and remaining scorpions. New and Old World buthids are also distinct lineages. Scorpionoids and the vaejovoid–chactoid lineage are the remaining major scorpion lineages. Chaerilidae and Pseudochactidae (*Chaerilus*, 21 species; *Pseudochactus ovchinnikovi*, from Kazakhstan) are monogeneric and enigmatic; they are like none of the other scorpion families and their relation to other major lineages is obscure. They may be basal buthoid groups.

Buthidae is the largest and most widely distributed scorpion family with approximately 74 genera and 531 species. Buthidae is most diverse in the African tropics and Palearctic regions. Buthids tend to have slender, elongate pincers, a robust tail, and usually a tubercle under the sting. All scorpions considered dangerous to humans are buthids. Buthids are also the most diverse ecologically and occupy humid, mesic, and dry habitats. The small family Microcharmidae is an Afro-tropical buthid segregate with two genera and six species.

The Scorpionioidea (36 genera and 355 species) is a large, monophyletic lineage that includes Bothriuridae, Diplocentridae, Heteroscorpionidae, Hemiscorpiidae, Ischnuridae, Scorpionidae, and Urodacidae. Scorpionidae lack a tubercle under the sting and the sides of the sternum are parallel. The family contains the genus *Scorpio* from the Mediterranean and Near East, much mentioned in classical Greek, Egyptian, and Christian myths, and *Pandinus*, the giant African black scorpion. The longest and heaviest scorpions are scorpionids, which are exclusively Old World.

The relationships and monophyly of the vaejovoid–chactoid lineages (43 genera and 495 species: Chactidae, Euscorpiidae, Iuridae, Scorpiopidae, Superstitionidae, Troglo-tayosidae, and Vaejovidae) are the most problematic areas of scorpion higher taxonomy and phylogeny. The large families Iuridae and Chactidae, in particular, are doubtfully monophyletic, although each includes many clearly valid groups. Together, the vaejovoid–chactoid lineages comprise about one-fourth of known scorpion species, including the most common species in North America.

Figure 5 Harvestman (Opiliones: Phalangidae, *Hadrobunus* sp.).

Opiliones

The described world fauna of Opiliones (harvestmen or daddy long legs) comprises approximately 44 families, 1554 genera, and about 5000 species (Figure 5). The largest harvestman is *Trogulus torosus* at 2.2 cm long. The anterior and posterior body regions are broadly joined and the abdomen is rather short, giving the body a wider and rounder appearance than those of other arachnids. The second pair of walking legs is usually the longest. Opilions have just two eyes (cave or litter groups are sometimes blind). All harvestmen have a pair of glands that open via large pores on the anterolateral margins of the body; the function of their secretions is apparently diverse. Harvestmen are the only arachnids in which males have a penis. Females have a long, flexible, and extensible ovipositor (as do many mites). The most common group in north temperate regions, the Phalangioidea (daddy long legs), have soft and flexible bodies, weak mouthparts, and extremely long legs (commonly 15 times the body length), but just as many harvestmen are fantastically armored with bizarre, huge chelicerae, raptorial pedipalps, and short, stiff legs. Others are mite-like, and still others are dorsoventrally flattened. Colors are usually subtle patterns of brown, gray, or black, but tropical forms can rival anything seen in spiders or mites. In the long-legged forms, the distal leg tip is divided into numerous false segments that form a prehensile tip. It can be wrapped around objects to achieve a very firm and adaptable grip. The long second legs may double as feelers.

The respiratory system is exclusively tracheate. The very long-legged Phalangioidea have accessory spiracles on distal leg articles. Touch and vibration perception, as in most other arachnids, seems to be the dominant sense. The eyes at best distinguish light and dark and direction of light. Opilions consume a broader diet than any other arachnids other than mites. The basic pattern is predation, but some, for example, specialize on snails, which are otherwise rarely consumed by nonacarine arachnids. Opilions also are known to eat dead insects, fruit, and decaying vegetable matter. Unlike other arachnids, harvestmen can ingest solid particles, as shown by sclerotized bits in their excrement.

Many harvestmen defend themselves against attack by shedding legs. One study of two species in Louisiana found

that about half the animals had lost one leg, but less than 10% lacked three. Seven-legged harvestmen seem to survive and function as well as intact animals. A shed leg continues to jerk and twitch attractively for minutes, permitting the harvestman to escape. All harvestmen have paired “repugnatorial” glands on the front margin of the body. When legs are pinched a droplet of fluid appears at the orifice which may be dabbed on an attacker with a leg or allowed to evaporate. The secretions can also help aggregating species to find each other, and some show broad antibiotic and antifungal activity, presumably useful to litter and soil dwelling forms. Quinones are a major ingredient. Soil dwelling harvestmen and the short-legged Laniatores are slow compared to long-legged harvestmen.

Ecology

In general, harvestmen prefer moist, or at least not xeric, environments. The mite-like Cyphophthalmi live in dark leaf litter, caves, or under stones. The largely tropical and usually short-legged Laniatores move slowly over vegetation or the forest floor. The usually long-legged Eupnoi can be anywhere, but their very long legs with prehensile tips are specialized for crossing the large gaps between the leaves of trees, shrubs, and herbs. The northern European opilionid fauna comprises approximately 24 species and that of North America approximately 235 species. In temperate regions, diversities of more than a dozen species per hectare are uncommon.

Reproduction

Uniquely among non-acarine arachnids, sperm transfer occurs via the male penis. Mating occurs quickly and seemingly without courtship. The male faces the female and pushes the penis underneath her body or between her chelicerae and into the gonopore. After insemination, the sexes separate and continue their solitary wanderings. Females use their long, flexible ovipositors to deposit eggs in suitably protected areas. Trogludids deposit their eggs only in empty snail shells, and other groups oviposit beneath stones, deep into soil, underneath bark, or in bore holes in plant stems left by insects, usually abandoning the eggs once laid. Newly hatched animals are active and resemble adults. Five to eight molts to maturity are common. An unusual reversal of sex role occurs in the Panamanian harvestman *Zygopachylus albomarginis*. Males fight to occupy existing mud nests or construct their own. Females wander between nests, courting the males, mating, and ovipositing in a series of nests. They have nothing more to do with the offspring. Males accumulate eggs of different ages and from different females and defend the eggs against conspecifics and ants.

Phylogeny and Taxonomy

The phylogeny of Opiliones has recently been clarified at the superfamily level, but many additional changes are expected in familial arrangements. Some families seem to be based only on primitive features (e.g., Travuniidae, Phalangodidae, and Triaenonychidae). Eupnoi and Dyspnoi classically formed the suborder Palpatores, but increasing evidence indicates that

this taxon is paraphyletic. The number of recognized families has approximately doubled in the past 20 years. At the species level the morphology of male genitalia is especially diagnostic.

Major Lineages

Cyphophthalmi

This suborder contains five (or six) families and about 100 species. It is sister to all remaining Opiliones (the “Phalangida”). Cyphophthalmi are eyeless, live in deep moist leaf litter or caves, and range in size from 1 to 7 mm. The animals have a hardened plate covering the entire dorsal surface, and they resemble mites. *Siro* is North American and European, but the family also occurs in Southeast Asia, Turkey, Japan, Mexico, and South Africa. Life spans of up to 7 years have been reported.

Eupnoi

This group contains two superfamilies, including the classic daddy long legs (Phalangioidae: Phalangiidae, Sclerosomatidae, Megalopsalididae, and Neopilionidae) of soft-bodied, long-legged harvestmen. *Phalangium opilio* is common around buildings and introduced throughout the world. The sclerosomatid *Leiobunum* spp. are common in North American and European forests, in which they move easily across the upper vegetation. They are predators and scavengers. Cad-doidea includes only one or two families of harvestmen with enlarged eyes and short legs, sometimes common on tree trunks.

Dyspnoi

This group also includes two superfamilies, but has many fewer species than Eupnoi. Ischyropsalidoidea contains three families and just seven genera. *Ischyropsalis* is European and feeds on snails. Trogluloidea contains four families, two monogeneric and several genera in the remaining families. *Nemostoma* is common in caves. Troglulidae are peculiar harvestmen that look like giant, flattened mites. Legs are very short. Troglulids live under stones and in leaf litter; snails are an important part of their diet.

Laniatores

This group is morphologically more diverse than the previous groups and tends to be more diverse in the tropics, including many colorful species. Three super-families are recognized: Traviunoidea (4 families), Oncopodoidea (1 family), and Gonyleptoidea (18–20 families). Colloquially, laniatorids are known as “short-legged” harvestmen because the most common laniatorids do have short legs, but some agoristenids, cosmetids, gonyleptids, caelopygines, progonyleptoidellines, and mitobatines have legs comparable in length to those of Palpatores. The Gonyleptoidea contains 18–20 families with raptorial pedipalps for prey capture and enlarged fourth coxae with spreading appendages—perhaps a defense against being swallowed whole by predators or dragged down the burrow of a parasitoid. Gonyleptidae are typical heavily armored and spiny, often colorful, and usually larger than 4 mm. They are exclusively Neotropical and, with more than 100 genera, are one of the largest families. The closely related Cosmetidae superficially resemble gonyleptids—large, heavily armored, often colorful, and slow-moving New World harvestmen.

Phalangodidae is a large cosmopolitan family of more than 150 genera defined mainly by the features they lack. For years it has been used to file taxa with no obvious relatives, and therefore its biology makes little sense. Although most diverse in the northern neotropics, their distribution includes southern North America. Their pedipalps are flattened with spiny margins.

Smaller Arachnid Orders

Amblypygi (whip spiders or tailless whip scorpions), Uropygi (whip scorpions or vinegaroons), Schizomida (no common name), and Palpigradi (microwhip scorpions) are all small, unfamiliar arachnid groups that are closely related to each other and to spiders (Figure 2). Like primitive spiders, all have two pairs of abdominal book lungs, although the second pair is missing in the tiny Schizomida and palpigrades lack both. The first pair of walking legs is elongate and feeler-like, with false articulations in the terminal articles to promote flexibility. Pseudoscorpiones (pseudoscorpions), Solifugae (wind spiders), and Ricinulei (no common name) are a miscellany of remaining arachnid orders related to various orders already discussed, as illustrated in Figure 2.

Amblypygi

Approximately 125 species of amblypygids in 20 genera and 5 families are known (Figure 6). The American *Acanthophrynus coronatus* is the biggest, at about 4.5 cm in body length. The usual adult body size is about 4–6 cm. The first walking legs of amblypygids are enormously long, and fully stretched a large animal can span 50 cm. Whip spiders have no tail, and their pedipalps are modified into fierce-looking, spiny raptorial appendages. Amblypygids are easily recognized by their extremely long front legs and raptorial pedipalps. Colors are dull brown or black. The body is flat and leg insertion twisted so that limbs fold in the same plane as the body (like a crab), permitting the animals to edge through thin openings such as

Figure 6 Whip spider or tailless whip scorpion (Amblypygi: Phrynidae, *Phrynus* sp.).

cracks in hollow trees. They move sideways more easily than forward or back. Amblypygids hunt by drifting their long front legs gently over the surface around them to locate prey and using their raptorial pedipalps to pounce. Like spiders, all the abdominal ganglia have migrated into the prosoma in which, fused, they form a brain. Reproduction is via a spermatophore. Like uropygids, amblypygid females carry their egg clutches inside a membrane of dried mucus glued to their ventral abdomens. The 15–50 young hatch and remain inside this membrane until they have undergone their first molt. The young cling to the mother for a short time.

Whip spiders live in subtropical and tropical areas, in forests and often in caves. They are exclusively nocturnal and fairly common. During the day they hide in hollow trees or logs, under loose bark, or under large logs. Only one species lives in leaf litter and is not known to burrow. Their diet seems to be a broad range of smaller arthropods in their environment.

Uropygi

About 100 species of whip scorpions are known in 16 genera and one family, Thelyphonidae (Figure 7). At 7.5 cm, the largest is *Mastigoproctus giganteus* of North America, but 3–5 cm is usual. Whip scorpions are easy to recognize by the long posterior whip or flagellum (highly modified terminal abdominal segments). Colors are brown to black. Uropygids have defensive anal glands that accurately spray an acid-smelling fluid at attackers. The smell explains the common name “vinegaroon.” The fluid of *M. giganteus* is 85% acetic acid but it also contains substances to reduce the surface tension of the epicuticle so that the acetic acid can spread widely and penetrate. Vinegaroons are supposedly not sensitive to their own spray. Reproductive habits are known only for a few species, but presumably sperm transfer occurs via a spermatophore glued to the substrate in all species. Some species have a lengthy courtship—10 hr to several days. Females keep their 12–40 eggs attached to their ventral abdomen. Female *Thelyphonus* build a deep burrow and do not feed

Figure 7 Whip scorpion (Uropygi: Thelyphonidae, *Mastigoproctus* sp.).

while guarding the eggs for 4 or 5 weeks. Uropygids may live 6–8 years or even longer.

Uropygids are tropical to subtropical animals. They hide in leaf litter, burrows, under logs and rocks, and inside dark crevices or holes during the day, emerging at night to hunt. Not much is known about their prey, but presumably it consists of other small ground-dwelling insects, arachnids, and crustaceans, which they crush between their pedipalpal segments prior to ingestion.

Schizomida

About 200 species in 30 genera and two families (Proto-schizomidae and Hubbardiidae) are known (Figure 8). Schizomids (there is no common name) are most like tiny uropygids, but the abdominal flagellum is short (three segments but rarely five). Colors are usually light yellow to tan to dull green. Assiduous searching in moist tropical litter usually turns up a schizomid. The largest schizomid known is *Agastoschizomus lucifer* at about 12.7 mm long, but 3 mm is typical. Most schizomids lack eyes entirely and live in moist tropical or subtropical leaf litter, under stones, in logs, moist crevices, caves, and so on. Reproduction is via a spermatophore attached to the substrate, after which females lay 6–30 eggs that are glued to the ventral female abdomen until the young emerge. At two Amazon sites schizomid abundances ranged from 5 to 110 animals per square meter per month.

Like the uropygids they have been reported to produce a defensive chemical smell. They can move backwards rapidly and have enlarged femora apparently used to hop backwards.

Palpigradi

There is only one family (Eukoeneniidae) with five or six genera and about 80 species. Palpigrades (microwhip scorpions) are tiny, light yellow to white, delicate soil and leaf litter specialists with a cosmopolitan distribution. The largest is *Eukoenenia draco* at 2.8 mm long, but 1 or 2 mm is typical. They resemble the young of Uropygi. Like whip scorpions,

Figure 8 Schizomid (Schizomida: Hubbardiidae) (photograph by Jeremy A. Miller).

they have a wide preabdomen and a multi-segmented whip-like postabdomen. Like many soil organisms, palpigrades lack most of the organ systems required by large animals that live in drier and less constant environments. They lack eyes, respiratory organs, and a circulatory system but have innervated setae that detect vibrations. Most species are known from the tropics; several palpigrades apparently live in intertidal or shallow marine habitats. *Eukoenenia janetscheki* was the only species found at two Amazon sites, but it was fairly abundant (30–120 animals per square meter per month).

Ricinulei

One family (Ricinoididae), three genera, and 53 species of ricinuleids are known (Figure 9). Ricinuleids, like schizomids and palpigrades, are soil-dwelling specialists. The largest is *Ricinoides afzelli* at 10mm. long, but most are 3–5 mm. Unlike the preceding forms, ricinuleids are heavily armored with a thick exoskeleton and a kind of visor or flap (the cucullus) that folds over the mouthparts. Colors are reddish to brown or black. Males have third legs modified for sperm transfer. Some have “eye-spots” that are able to sense light. Females lay one or two eggs at a time, which they may carry about with them. Adults may live 10 years. Formerly thought to be extremely rare, ricinuleids are not uncommon in Neotropical leaf litter. They are also known from Africa, but not from the Asian tropics.

Pseudoscorpiones

About 3100 species of Pseudoscorpions (or “false scorpions”) have been described, classified in approximately 430 genera, 24 families, and two suborders (Epiocheirata and Iocheirata) (Figure 10). The North American fauna comprises about 350 species. One local fauna in the Amazon comprised nine species and Mediterranean ecosystems around Perth, Australia,

Figure 9 Ricinuleid (Ricinoididae).

and other Old World tropical moist ecosystems are comparable (M. Harvey, personal communication). Pseudoscorpions look like tiny scorpions without the tail and pectines. Colors are tan to dark brown or black. Their chelate pedipalps can have venom glands and the chelicerae have silk glands. The largest is *Garypus titaneus* at 12 mm long, but most are 2 or 3 mm. They are flattened for life in crevices, usually under bark or in leaf litter, but a few forms live on ocean shores where they are truly intertidal. Numerous species live among the hairs of mammals where they feed upon other arthropod parasites. At least one species has the body, legs, and palps modified for living on a Celebes rat. *Chelifera cancrivora* is cosmopolitan and lives in houses where it hunts book lice and other small insects. Pseudoscorpions are sometimes found in aggregations of dozens of individuals. Reproduction, as in most other arachnids, is via a spermatophore. The female builds a silken nest and secretes a "brood sac" attached to her body and in which she nourishes the 3–40 embryos with maternal secretions. Juveniles leave the mother soon after hatching. Pseudoscorpions are famous for their tendency to disperse by phoresy. Mature females (rarely males or juveniles) use their pedipalps to hold onto larger insects, which carry them from place to place as they fly about. Phoretic specimens in fossil amber show that this behavior is at least 10 million years old.

Solifugae

About 1065 species of solifuges are known, grouped in about 153 genera and 12 families (Figure 11). The greatest known diversity occurs in Namibia. Wind spiders (sun spiders or camel spiders) look somewhat like hairy, stout, fast-running spiders, but their chelicerae are fearsomely enlarged and both the leg-like pedipalps and the long and slender first legs are used as feelers. The fourth femurs bear ventral sensory structures shaped like inverted mushrooms. Colors are tan to sandy yellow. The largest is *Galeodes caspius* at 7 cm, but 2 or 3 cm is usual. Wind spiders can run extremely fast (53 cm/sec) for short bursts, but like most arachnids they cannot sustain rapid

locomotion for long periods. The solifuge respiratory system is only tracheate and is comparable in complexity to that of insects. They are generally nocturnal and exclusively carnivores and, like any of the larger arachnids, will take small mice, lizards, amphibians, and so on if the opportunity arises. A few species feed only on termites. Unlike most other arachnids, solifuges are active, cursorial predators. Wind spiders are most common in tropical and subtropical dry or desert regions, but they are absent from Australia. Many inhabit burrows, where they may stay up to 9 months of the year, depending on rainfall. Reproduction is via spermatophore, which the male produces during courtship and transfers into the female gonopore with his chelicerae. The female digs a deep burrow to deposit egg masses that may contain 5–164 eggs. Females may lay 1–5 egg masses. Some females remain with the eggs until hatching. Newly hatched wind spiders are gregarious and remain in the burrow for the first two molts.

Acari

Mites and ticks are classified as Acari, from a Greek word meaning a thing too tiny to be divided (Figure 12). At more than 45,000 species, Acari is already the most diverse arachnid order, but acarologists estimate that between half a million and more than 1 million species actually exist. Despite being far more abundant and diverse than any other order of arachnids, mites and ticks are nonetheless much less familiar to most people than spiders, harvestmen, or scorpions. Likewise, scientific knowledge of mites lags far behind our understanding of most other arachnid groups. The primary reason for both public and scientific ignorance of mites is their small size.

Since we sometimes find them on ourselves and our pets, because they are relatively large, and because of their role as serious vectors of human disease, the ticks are probably the most familiar group of mites. In fact, ticks (which have their own name only because of their importance to humans) represent a small offshoot on the evolutionary tree of mites. Other kinds of mites are vastly more common and diverse

Figure 10 Pseudoscorpion (Pseudoscorpiones: Neobisiidae, *Tartarocreagus infernalis* (Muchmore) (photograph by James C. Coken-dolpher).

Figure 11 Wind spider or solifuge (Solifuga: Eremobatidae).

than the ticks and include not only other parasites but also followers of many other ways of life. In this article, unless otherwise distinguished, the term *mites* is intended to include ticks and will be used interchangeably with Acari.

The Acari are distinguished from other arachnids principally by the lack of conspicuous body segmentation, the broad union of the leg-bearing part of the body (the podosoma) with the posterior part (the opisthosoma) to form a single unit (idiosoma), the aggregation of the mouthparts into a distinct anterior body region (the gnathosoma), and the first active immature stage, the larva, having only three pairs of legs. The gnathosoma is not a true head, like that of an insect, in that it possesses neither eyes nor antennae and does not contain the brain. (Most mites have no eyes at all, but those that do bear them on the idiosoma.) The brain is situated anterior to the stomach in the idiosoma.) Although usually compact in form, like that of a spider mite or tick, the overall shape of the mite body varies greatly. Species that live in polypore fungi or hair follicles are elongated to fit their habitat, and mites found deep in soil tend to be worm-like. Ticks and some other mites can tolerate enormous distention of the body wall to accommodate food.

Like other chelicerate arthropods, mites have no antennae, but in many groups the first pair of legs carry chemosensory and tactile organs and are not used, or little used, for locomotion. The pedipalps, integrated laterally into the gnathosoma, are also primarily sensory in function. The chelicerae, the primary food-getting organs, vary greatly in form, in accord with the varied feeding habits of mites. In many species, the chelicerae of males are so modified for sperm transfer that adult males scarcely feed.

Ecology

Mites are found in virtually every habitat on Earth. On land, legions of free-living mites populate soils in all habitats, often numbering in the hundreds of thousands per square meter in the soil (50,000–250,000 per square meter, down to 5 cm depth, in forests; 20,000–100,000 in grasslands; and 500–1000 in deserts). In many soils, including deserts, mites can be found at depths up to 10 m, where they follow plant root systems. Although the habits and behavior of many soil

mites remain a mystery, it is known that soil mites fill many ecological roles. Many eat decaying organic matter (and the microorganisms it contains); others consume fungi, algae, and bacteria; and still others are predators, feeding on nematodes, other mites, or various stages of insects. Oribatid mites in the soil facilitate plant growth by dispersing the spores of mycorrhizal fungi, which form mutually beneficial and often essential associations with higher plants.

Mites are common and often abundant on plants, on which many species feed on leaf, stem, or root tissue by piercing cell walls. Others specialize on plant reproductive parts, including nectar, pollen, and fruit. Still other plant-dwelling mites are fungivores (eating fungi on leaves or stems) or predators, mostly of plant-feeding mites. Unlike life in the soil, life on plant surfaces constantly threatens mites with desiccation. Hiding from direct sun on the underside of leaves offers some protection because the “boundary” layer of still air is kept relatively moist by plant transpiration.

In addition, many plants produce domatia—hollow, mite-sized cavities or pockets in the leaf. The adaptive function of domatia is controversial, but experiments have shown that removal of domatia from some plants that normally have them reduces the density of beneficial predatory mites and increases the density of herbivorous mites.

Some fungus-feeding mites have specialized cavities or pouches in the body wall (sporothecae) in which they carry spores or propagules of fungi that they depend on for nourishment.

Parasitic and phoretic mites exploit most terrestrial vertebrate species, most other arthropod groups, mollusks, and even marine invertebrates (Figure 13). Most species of birds, for example, generally support many “feather” mite species found nowhere else. Four or five different, host-specific species inhabit different feather types (flight feathers, tail feathers, or body feathers), whereas different species live on the surfaces of feathers, others in the interior lumen of the quills, others on or in the skin, and yet others in the nasal passages. One particular species of parrot hosts more than 20 species of feather mites. Bird nests support additional, phoretic species that feed on debris or on other nest associates. Both parasitic and phoretic species generally colonize young birds while in the natal nest and travel with the host until it builds its own nest. Similar sets of species inhabit the bodies of mammals and reptiles and, to a lesser degree, amphibians.

Figure 12 Free-living yellow moss mite (Acari: Penthalodidae, *Stereotydeus* sp.) (photomicrograph by David Evans Walter; scale bar = 100 μ m).

Figure 13 Predatory sejine mite (Acari: Sejidiidae, *Epicroseius* sp.) (photomicrograph by David Evans Walter).

Mites are also common associates of insects and other invertebrates. Some are parasitic and deleterious to their hosts, such as the tracheal mite and *Varroa* mite parasites of honeybees or moth ear mites. Some are commensal (e.g., feeding on insect waste products). Others are believed to benefit the host, perhaps by consuming other harmful mites, parasitic nematodes, or decaying matter that would otherwise nourish fungi or bacteria that might threaten the host or its young. Some insects have acarinarium, special pockets in the outer body wall, that are routinely occupied by phoretic mites. The very existence of acarinarium, which have no other known function other than to house and transport mites, is evidence for a net beneficial relationship between these mites and their insect hosts. Parasitic mites have been shown to be capable of mediating horizontal gene transfer between insect host species.

All ticks require blood from a vertebrate host for development and reproduction but live off the host when not feeding or mating. Chiggers and many other mite species must live a portion of their lives, and others all their lives, as parasites of animals. Other mites exploit animal hosts not for food but strictly for transport—a phenomenon called phoresy (see the following section). Parasitism is thought to have evolved, in some lineages, from phoretic associations.

Mites are common and diverse inhabitants of freshwater and marine habitats. In fresh water, adults and nymphs prey on other mites, crustaceans, and aquatic insects. The larvae of aquatic mites are commonly parasitic on insects and crustaceans, and nymphs and adults of unionicolid mites parasitize bivalve mollusks. Other aquatic mites graze algae and fungi growing on aquatic plants. Mites are common on seashores, including the intertidal zone. The sea is home to predatory and algae-feeding mites. Some mites have been found at depths up to 7000 m at hydrothermal vents, and one group lives in the gut of sea cucumbers. Mites are the only arachnids found in the ocean depths.

Closer to home, even the cleanest office, classroom, or home normally supports dust mites (e.g., *Dermatophagoides* spp.), which live on organic matter in house dust. Some mites are stored-product pests, feeding on grains, cheese, and other dry foods. Even more intimately, as you read this encyclopedia there is a very good chance that the follicles and sebaceous glands of your forehead or eyelids house normally benign, microscopic mites (*Demodex* spp.).

Reproduction and Dispersal

Reproductive patterns in mites are remarkably diverse. Many mites are ordinary diploids (having an equal number of chromosomes from each parent) with two sexes, requiring fertilization by the male for females to reproduce. In other groups, males are absent, and females bear female young from unfertilized eggs. In still other mites (e.g., spider mites), females require sperm from a male to produce (diploid) daughters, but sons are haploid (they have only the maternal chromosomes) since they are produced from unfertilized eggs. In other species (e.g., some phytoseiid mites), both sexes are diploid and all eggs require fertilization to develop, but only the mother's chromosomes are active in males (called paternal genome loss).

Modes of sperm transfer are diverse. Some mites transfer sperm directly through copulation, using legs, palps, or other specialized body parts to accomplish the transfer. Other mites rely on spermatophores placed on the substrate, with or without active enticement of the female to take up the sperm.

Development of the egg takes place in most mites after oviposition. In some species (e.g., moth ear mites and hummingbird flower mites) the eggs are laid *communally*. In other mites, the young leave the mother's body as active larvae. In some mites (e.g., *Siteroptes graminum*) sisters and brothers both hatch and mate within the mother's body, and both mother and sons die when the fertilized daughters emerge—truly material for a Greek tragedy.

The development of most mites includes one or more active stages between egg and adult. (Some Heterostigmata have no active immature stages.) In nearly all groups, the first active immature stage, called the larva, has three pairs of legs, and later stages, including the adult, have four pairs. (The plant-parasitic Eriophyoidea are exceptional in having two pairs of legs in all active stages, and females of many species of insect parasitic Podapolipidae have three, two, or even only one—the anterior—pair of legs.) The number of nymphal stages between larva and adult varies from none to three, depending on the group. Several groups of mites have metabolically inactive stages that can endure stressful periods. Life expectancy among mites also varies widely. Some mites live only about 1 week or so (e.g., hummingbird flower mites), whereas others require several years to complete the life cycle (e.g., certain ticks, oribatid mites, and water mites).

Because mites are so small and (unlike most insects) are wingless, selection for effective dispersal from one food patch to another has produced many special adaptations. Parasitic mites, for example, must have a way to find a new host—or ensure that their offspring do—before the current host dies or becomes unsuitable. In the case of plant-feeding mites, some species disperse aerially, either by simple passive transport in the wind or, in the case of some spider mites (Family Tetranychidae), by “ballooning” on strands of silk. (The silk-producing glands in these mites are not homologous to those of spiders.) Other plant-feeding mites disperse phoretically on plant-visiting animals. For example, nectar- and/or pollen-feeding insects and birds on all continents carry nectar- and/or pollen-feeding mites as hitchhikers—a way of life that has many independent evolutionary origins.

Some groups of mites have special, non-feeding stages adapted for phoretic dispersal. In others, adults and sometimes later nymphal stages mount phoretic hosts to reach new hosts or habitats when local mite population density becomes high, when the host is ready to disperse (e.g., emerging adult insects), or when a food plant becomes unsuitable.

Phylogeny, Taxonomy, and Current Knowledge

Only 90 species of Acari were known to Linnaeus, all of which he placed in the genus *Acarus*. Currently, perhaps 45,000 species in 431 families and 3672 genera have been described compared to 30,000 species estimated 30 years ago. The rate of description of new species is still very high—several hundred species per year—and every systematic acarologist has dozens or hundreds of undescribed species sitting on shelves in vials

of alcohol, awaiting description and classification. In fact, the taxonomic impediment to full knowledge of the Acari is monumental:— The number of practicing, modern mite systematists is no more than 50, and the rate of training of new systematists is alarmingly low. Moreover, exploration and species discovery in tropical forests (especially the forest canopy), lakes, and streams is still in its earliest stages. Most estimates of the total world fauna of Acari range from 500,000 to more than 1 million species, but some acarologists even suggest that mites rival insects in worldwide number of species. In any case, mites represent by far the most species-rich and ecologically diverse arachnid group. **Table 1** gives summary data on mite diversity.

Major Lineages

Given the highly incomplete knowledge of the Acari, it is not surprising that their phylogeny, classification, and nomenclature are far from settled. It is generally recognized, however, that the Acari comprise three lineages that diverged from one another in very ancient times: the Opilioacariformes and Parasitiformes (which together constitute the Anactinotrichida) and the Acariformes (which constitute the Actinotrichida). Their relationships to one another and to non-acarine arachnid groups have been debated for decades, but the current opinion appears to be that the Acari, so defined, is a monophyletic group.

The taxonomic rank of acarine lineages is also controversial. The tradition among zoologists in general and arachnologists is to treat Acari as an order, but acarologists now treat it as a subclass or even a class, with subsidiary mite taxa then being orders or superorders. Clearly, this is not the place to attempt a resolution of this controversy. The taxonomy in the following sections reflects the prevailing acarological point of view that major groups should rank as orders, despite the incongruity with the rest of this article.

Order Opilioacariformes

The small order Opilioacariformes (with 17 species described of an estimated 85–170 total) with a single family (Opilioacaridae) are large mites (1.5–2.3 mm in length) that somewhat resemble small harvestmen. Some genera occur in dry climates, often under litter or stones, and others in tropical forest litter, where they feed as omnivores or predators.

Order Parasitiformes

The Order Parasitiformes includes three Suborders: Holothyrida, Mesostigmata, and Ixodida.

Suborder Holothyrida The Holothyrida is a small group (with 32 species described, of an estimated 160–320 total) of large (2–7 mm) saprophagous and predaceous mites of temperate and tropical forest litter, known only from Pacific-Indian Ocean islands and the Australasian and Neotropical regions.

Suborder Mesostigmata The cosmopolitan suborder Mesostigmata, in contrast, is extremely rich in species (with 11,632 species described of an estimated 100,000–200,000 total) and diverse in habits, ranging in size from 0.2 to 4.0 mm. Mesostigmatic mites range from saprovores (eating dead or decaying organic matter), fungus feeders, predators living in

soil, litter, beach wrack, dung, or rotting wood, to pollen and nectar feeders. Repeatedly, mesostigmatic lineages have evolved close relations with other arachnids (spiders, amblypygids, and scorpions), myriapods, insects, and vertebrates and their nests. Some are endoparasitic (living inside vertebrate respiratory tracts), and others are ectoparasitic. Many others are phoretic, with a variety of feeding habits. Some prey on mite and insect pests of orchards and stored food products. Some of these beneficial predators have been genetically engineered to be more acaricide resistant, enhancing integration of biological and chemical control of pest mite species.

Suborder Ixodida With 880 species described, of an estimated 1000–1200 total, the ticks (suborder Ixodida) are taxonomically the best-known major group of Acari primarily because of their medical and economic importance. Ticks are considerably larger than most other Acari; adults range in size from 1.7 to 12.7 mm in the unfed state. All ticks feed on the blood of terrestrial vertebrates as ectoparasites. (Sea snakes also have ticks.) Ticks are capable of carrying and transmitting to humans and their domesticated animals more kinds of disease-causing organisms than any other group of blood-feeding arthropods. These agents include viruses, spirochaetes, rickettsiae, anaplasmas, bacteria, piroplasma, and filariae. Important tick-borne human diseases include Russian spring–summer encephalitis, Colorado tick fever, African relapsing fever, Lyme disease, Rocky Mountain spotted fever, Siberian tick typhus, Q-fever, monocytic and granulocytic ehrlichiosis, Kyasanur forest disease, and tularemia.

Order Acariformes

The order Acariformes comprises three suborders—Prostigmata, Astigmata, and Oribatida—with a fourth group, the Endeostigmata (120 described species, perhaps 1200–2400 total) of uncertain rank and affinities but often treated as Prostigmata.

Suborder Prostigmata Prostigmatic mites (with 17,000 described species of an estimated 320,000–640,000 total) range in size from 0.1 to 2 mm, with a few of the giant red velvet mites as large as 16 mm, and vary widely in body form, color, habitat, and feeding adaptations. They include predatory and omnivorous species living in organic strata of soils and on algae, lichens, mosses, trees, and shrubs. The Prostigmata also include obligately plant-feeding groups, including the spider mites (Tetranychidae), false spider mites (Tenuipalpidae), and eriophyoid mites, many of which are serious economic pests of field crops, orchards, and greenhouse plants, in some cases acting at vectors of damaging plant viruses. Some groups inhabit the soil; species of the family Nematalycidae have been found at depths of up to 3 m in sand dunes. Species of at least five families of prostigmatic mites are known from Antarctica, and others live in caves. Some prostigmatic groups live in the sea, where they are predaceous or algivorous. Many families of this order are specialized for life in springs, streams, rivers, waterfalls, lakes, bogs, or aquatic interstitial habitats of all descriptions. Some groups live in thermal waters; mites of the genus *Thermacar* inhabit hot springs, thriving in water up to 50 °C, in which

the larvae parasitize amphibians. As in the Mesostigmata, parasitism has arisen repeatedly in independent lineages within the Prostigmata. Some are ectoparasites of slugs, scorpions, insects, or vertebrates; some are parasitoids of eggs or larvae of insects; and some are endoparasites of insect respiratory and reproductive organs, vertebrate respiratory tracts, the quills of birds, the skin of turtles, the mantle cavity of mollusks, the guts of echinoderms, or the gills of decapod crustaceans. A few species in the order are vectors of human disease (scrub typhus), and some cause mange and other skin diseases in domesticated animals. *Demodex* spp, which live (generally benignly) in hair follicles and sebaceous glands of the human face, are prostigmatic mites, as is the straw itch mite *Pyemotes tritici* which can cause severe skin lesions in humans.

Suborder Oribatida The Oribatida is remarkable in being the only major group of mites in which a great diversity of species (11,000 described species of an estimated 33,000–110,000 total) has evolved without the evolution of parasitism. Although a few species are phoretic as adults on insects, the rest of this vast radiation are free-living inhabitants of the soil, forest litter, tree holes, bark, twigs, leaves, mosses, lichens, algae, freshwater vegetation, bogs, and the intertidal zone. Most oribatid mites feed on fungi, but some consume dead woody material or algae, and a few are predators on nematodes, rotifers, and other small invertebrates. Oribatida (and many species classified as Astigmatata, which are actually derived oribatids) feed on panicle matter. Through their feeding, they help to maintain soil structure. Unknown for other mites, many oribatid species sequester calcium and other minerals in their thickened cuticle. As with Prostigmata, oribatid species are also found on continental Antarctic. Some oribatids are intermediate hosts of cestode tapeworms whose final hosts are herbivorous mammals. Oribatid mites range in size from 0.2 to 1.5 mm.

Suborder Astigmata The Astigmata, closely allied to the Oribatida, are primarily associates of arthropods, vertebrates, and other animal groups, although a few species are free-living in all life stages (with 4500 described species of an estimated 90,000–180,000 total). This lineage is thought to be derived from within the Oribatida, but a revised classification, with names of major groupings to reflect this relationship, has yet to be promulgated. A key evolutionary innovation of the Astigmata is a nonfeeding, immature stage especially adapted for phoretic dispersal or tolerance of adverse conditions. Astigmatic mites include fungus feeders, a few plant feeders, a few predators, and mites with mouthparts specialized for filter feeding in water. Some feed on algae in the intertidal zone, in water-filled tree holes, or in sap exudates. Several groups inhabit the nests of insects, mammals, and birds as ectoparasites or commensals. The specialized deutonymphs in several families are parasitic in the hair follicles of mammals. The insect hosts of some species produce acarinarium. One group lives as commensals on the gills of hermit crabs. A large radiation of astigmatic mites lives on feathers and within quills of birds as well as in the avian respiratory tract and air sacs. Another group has radiated among mammals as parasites of the skin, hair, follicles, respiratory passages, ears, and even (rarely) the digestive tract. Some

astigmatic mites feed in dung or carrion, and others are important pests of stored food products, including not only grains but also stored meat and dried fish. This order also includes house dust mites (*Dermatophagoides* spp.), the itch or scabies mite (*Sarcoptes scabiei*), and mange mites.

Acknowledgments

We gratefully thank Valerie Behan-Pelletier, Clifford Desch, Mark Harvey, Gustavo Hormiga, Adriano Kury, Evert Lindquist, Roy Norton, Barry O'Connor, Lorenzo Prendini, Heather Proctor, Jeffrey Shultz, William Shear, and David Walter for comments on the manuscript, whole or in part. Estimates of mite species numbers are based on Walter and Proctor (1999).

Glossary

Arboricolous Tree inhabitants (“arboreal”).

Assemblage Collective occurrence of several individuals representing the same species or several species without interspecific relationships.

Bionomics Mode of life of a species.

Biotope Characteristic living space, of distinguishable nature compared with its environment, of a (bio) community (also “(bio)coenosis”).

Bivoltine Species with two generations per year.

Community Collective occurrence of individuals representing several species with, at least in part, interspecific relationships (also “coenosis”).

Flood resistance Submersion ability of weeks or months.

Flood tolerance Submersion ability of few hours up to several days.

Habitat Characteristic living space or site of a species.

Plastron Thin layer of air, held by specific body structures, into which oxygen from the surrounding water is added by means of Diffusion to the same extent as oxygen is withdrawn by breathing.

Plurivoltine Species with several generations per year (also “multivoltine”).

Quiescence Dormancy in which inhibition of development depends directly on environmental factors.

Terricolous Soil inhabitants.

Univoltine (Bivoltine) Species with one (two) generations per year.

Taxa and Number of Species

Approximately 2% of the world's Arachnida and 3% of the Myriapoda live in Amazonia. However, Ricinulei represent 28%, Schizomida and Scolopendromorpha 9%, and Paur-opoda more than 7% of species known worldwide in the respective taxa (Table 1). To estimate the extant species in Amazonia is difficult, especially in those cases in which numbers differ by two or three different orders of magnitude from the species described worldwide. For mites which, like spiders, are considered as a mega- or hyperdiverse taxon in the Arachnida, opinions of taxonomists differ substantially. This is also due to different methods used to derive such estimates (Platnick, 1999). In millipedes, ~250 species have been described from the Amazon drainage basin but 5000 are estimated to exist (Table 1). This is based on the assumption that most genera originated in the Andes, where most of the known species now occur but there have been few sampling efforts.

Megadiversity and high densities are attributed to Neotropical insects, in particular those inhabiting forest canopies. The dominant taxa in the canopy of nonflooded primary forests in Central Amazonia are Formicidae and Diptera. In studies by Guerrero in 1995 and 1996 near Manaus (Reserva Ducke), these two taxa represented 52% and 10%, respectively, of the 325 arthropods per square meter obtained on average by fogging the canopy of 40 trees (nine species of the families Sapotaceae and Lecythidaceae) once each during the dry and rainy seasons. In another study in this reserve, two canopies of a widely distributed Amazonian tree, *Goupia glabra* Aubl. (Celastraceae, height 38 and 45 m) were fogged in intervals of 6 or 24 months (1991–94). A total of 95 ant species were found on a single tree. In comparison, there are 105 ant species recorded from all over Germany. Of the 124 ant species obtained from both trees, more

than one-third were represented by singletons, that is, one specimen per species. Data also indicated a biotic interaction between predatory ants (probably *Crematogaster* spp.) and the gall-building Cecidomyiidae and between Cecidomyiidae and the parasitic Hymenoptera. This was not determined from previous studies in the tropical canopy (Adis *et al.*, 1998a).

Comparative with the high density and biodiversity of Formicidae and Diptera in tree canopies is that of Acari and Collembola on the forest floor. These two taxa represent between 50% and 80% of the 26,000–74,000 terricolous arthropods extracted per square meter from 14 cm soil depth in nonflooded “terra firme” forests of Central Amazonia. However, owing to taxonomical difficulties in both groups, data on species diversity are scarce and based on adult animals, although just as many immatures have been caught. The highest number of oribatid mites, 97 morphospecies, were reported by Wunderle from a primary forest near Pucallpa, Peru. In the Manaus area, Franklin found 71 and 74 morphospecies of oribatid mites in a primary forest on yellow latosol and on white sand, respectively, and 57 morphospecies in a 3-year-old secondary forest on yellow latosol (previous primary forest that was cut and burned). The ratio between the total number of specimens and morphospecies decreased accordingly, being 53.3, 36.3, and 22.8, respectively. In the same forests, Oliveira obtained 74, 65, and 65 morphospecies, respectively, of Collembola (53–64% represented Isotomidae and 7–16% Entomobryidae), but specimens: morphospecies ratio was lowest in the primary forest on white sand (49.5) compared with the primary and secondary forests on yellow latosol (67.6 and 61.8, respectively). Statistical analysis of data indicated that morphospecies similarity is dependent on both the nature of the soil (in springtails) and human disturbance (in oribatid mites). Only 32 oribatid morphospecies were obtained from pastures near Manaus.

Table 1 Families, genera, and species of taxa representing the Arachnida and Myriapoda in the world and in Amazonia (up to 1999) as well as estimates of existing species (fossil taxa not included)

Origin and Geographical Distribution of Species

Little is known about the centers of evolution and dispersal for arthropod taxa that occur in Amazonia. Several pathways are currently being discussed.

Origin in the Neotropics with a Generally Wide Range of Geographical Distribution (Chilopoda: Scolopendromorpha)

No scolopendromorph taxon of generic level is known as Amazonian endemic as it is at least present in other areas of

the Neotropical realm. Studies of Schileyko showed that only 25% of the total 52 species currently known in Amazonia, representing 6 of the total 11 genera, seem to be endemic. The wide geographical distribution might be related to the relatively large size, high mobility, swimming ability, and predaceous mode of life of an ancient group.

Origin in the Andes and/or the Guyanian Shield and Subsequent Dispersal into the Amazon Basin (Archaeognatha: Meinertellidae, Coleoptera: Carabidae, Diplopoda: Polydesmida)

Representatives of the Meinertellidae probably advanced from the Andes into the lower situated forests of the Amazon Basin. During this process, the formerly petrophilous animals, inhabiting mountain floors, adapted to an arboricolous mode of life in the trunks and canopies of trees. They even acquired a vertical jumping ability on the tree trunk, which was found for the first time in the arboricolous species *Neomachilellus adisi* in a black-water inundation forest of Central Amazonia. In these periodically flooded forests, the Meinertellidae succeeded to colonize the forest floor as well. Flood resistance of eggs (observed in *N. scandens*) and the determination of egg development by the flood pulse (= quiescence duration correlated with the period of inundation) are prerequisites for a potential distribution on the waterway (on logs or floating meadows). *N. adisi* was also found in an inundation forest above Leticia (Columbia) and might have reached Central Amazonia on the Rio Solimões-Amazonas. Similarly, the *Neomachilellus* species which currently inhabit the Caribbean and the coastal regions of the United States might originally have been transported by ocean currents from the mouth of the Rio Amazonas and the Rio Orinoco to these areas. An actually waterproof, resistant blastoderm cuticula and a presumably long duration of egg development during transportation (1 year or more, as in European species) certainly favor a geographical distribution on waterways. An interruption of the quiescence owing to drying of the means of transport used, a rapid eclosion of juvenile animals, and a fast achievement of maturity (all observed in *N. scandens*) favor the new colonization of a biotope as well. Useful for this colonization is the swimming ability and a temporal survival on the water surface (flood tolerance), which was reported for several species of the Machiloidea (Adis, 1992; Sturm, 1984).

Erwin and Pogue presented biogeographical maps with centers of endemism, based on taxa distribution and cladograms, for sister groups of the arboricolous carabid beetles genus *Agra* from Neotropical forests. Patterns of species evolution are directed, in part, from the North Atlantic coast (including the northern Guyanian shield) to upper Amazonia (*palmata* lineage) and from the North Atlantic coast to either upper and middle Amazonia or lower Amazonia (*erythropus* lineage). According to Erwin (1991), these hypothetical "centers and corridors of radiation" can be discovered and targeted for long-term protection through analyses of diverse arthropod groups (beetles in particular) and detection of congruent patterns among radiation lineages.

Origin in Nonflooded and/or Floodplain Forests of the Amazon Basin (Scorpiones, Chilopoda: Geophilomorpha)

Many scorpion species apparently require strict environmental conditions and thus are found only in narrow zones of distributions. Very few species currently known from eastern Amazonia are present in western Amazonia. One of the four principal "corridors of distribution" (or radiations) in South America is located in Central Amazonia. Rupture zones and ecobarriers between these corridors are attributed to geohistorical events. For instance, the rupture zone of distribution found in the region of the Orinoco delta might be due to the proposed existence of a large inland lake in Central Amazonia during the late Pleistocene and early Holocene (Lourenço, 1994).

In the Geophilomorpha, half of the ~100 Neotropical species representing the genera *Schendylops*, *Pectiniunguis*, and *Ribautia* seem to be endemic to areas identified as Pleistocene forest refuges (see Species Richness: Causes and Maintenance) based on evidence from woody angiosperms (Prance, 1982). Valleys of the major rivers (Amazon, Orinoco, Paraná, and Paraguay) are suggested to be the main routes of subsequent distribution, even to high-altitude sites (Pereira *et al.*, 1997).

Origin in Treeless Floodplains of the Amazon Basin (Coleoptera: Carabidae)

According to Erwin, the main centers of evolution in carabid beetles are open floodplains along rivers or lakeshores in the equatorial tropics with somewhat stable conditions. Taxon pulses which effect these flying and highly vagile waterside generalists caused, by means of adaptations, their dispersal in three directions: (i) colonization of treetops (canopy specialists), (ii) colonization of mountains (altitude specialists), and (iii) colonization of temperate regions (climate specialists). For the colonization of temperate regions, seasonality is considered as a basic requirement. Seasonal changes, primarily owing to periodical precipitation (= primary or ultimate ecofactor), cause seasonal inundations in riverine habitats (e.g., Central Amazonia) or dryness of the soil owing to a decreasing river level (e.g., East Zaire). Both situations cause an interruption of the reproduction in carabid beetles during these unfavorable conditions. They induce a gonad dormancy which is regulated by changing temperatures in the habitat (= secondary or proximate ecofactor). For this reason, Central Amazonian inundation forests have been postulated to represent one of the locations at which seasonality has been generated in carabids and other arthropods (Adis, 1992; Erwin, 1998).

Species Richness: Causes and Maintenance

Biological diversification in the Neotropics is the subject of ongoing and frequently antagonistic discussions. Several theories have been proposed to explain the high species richness of Amazonian plants and animals, mostly in a deductive sense, based on selected groups. Studies on distribution patterns aim to detect centers of endemism. It is hoped that biogeographical maps, now also based on cladistic methods, will elucidate evolutionary patterns among these centers.

However, it is accepted that databases are still insufficient (with the possible exception of those for birds) for the type of detailed study needed to understand distribution patterns for most Neotropical groups. Full knowledge of distribution will not be obtained until we understand what sets the limits, for example, the edges of species distribution (Vanzolini and Heyer, 1988).

Past assessments of this type have been based mostly on the presence of Pleistocene refugia (*see* Origin and Geographical Distribution of Species), also called the "Haffer effect." This is the theory that Neotropical forest fragmentation occurred during northern ice advances due to Milankovitch cycles and the temporary existence of forests and grasslands (savanna), called "island" refugia, that caused temporal centers of endemism (Haffer as cited in Prance, 1982; Haffer, 1996).

Studies on 162 species of Neotropical butterflies (Nymphalidae) by Brown indicated the existence of 50 principal forest centers of evolution and endemism. Smaller areas, recognizable as 38 forest refuges, presumably acted during the last major dry, cold spell in the Quaternary (20,000–13,000 years BP). Studies by Erwin and Pogue on arboricolous carabid beetles, adapted to life in Neotropical forest canopies (genus *Agra*), showed that species group distribution is much broader. In this case, areas considered to be centers of endemism are geographically larger than that in butterflies and vertebrates (Prance, 1982; Vanzolini and Heyer, 1988).

Haffer's forest refuge model as stated deals only with nonflooded terra firme forests, their fragmentation, and/or replacement by savannas (*sensu lato*). There has been no indication that riverine forests disappeared along the lengths of rivers, but rather it appears that savannas were behind such

forests as they are today. For this reason, Erwin and Adis consider Central Amazonian floodplain forests, especially along black-water rivers in the Negro delta (called igapó), to be short-term refuges and long-term evolutionary centers (Prance, 1982; Adis, 1984). Flood cycles greatly influence speciation rate and dispersion of arthropods. Evidence from Rio Tarumã Mirim, an affluent of the Rio Negro above Manaus, suggests alternation of two types of inundation: annual flooding and continental water table rise during the past million years. The area examined originally was covered by a nonflooded terra firme forest. Periods of high sea level caused a backup of main riverine courses in Amazonia. During these periods, the affluent Tarumã Mirim was high enough that annual water fluctuations of the Rio Negro led to an inundation lasting several months in the forest under study. The first inundation was several million years ago. Since that time, various periods of high sea level (according to Fairbridge) have occurred (e.g., 250,000, 170,000, and 85,000 years ago; Figure 1), with annual flooding of 10,000–30,000 years duration. Approximately 6000 years ago, the sea level reached a height of about 5 m below mean sea level. Since then, the examined forest has been inundated again. Flood cycles were responsible for extant vegetation formation in the igapó. During high sea level, the (lower) bank of the Rio Negro suffered longer periods of inundation and, according to Sioli, possible formations of large "ria lakes." Igapó forests were drowned (at least partially) and backed up minor tributaries which subsequently had annual flooding (e.g., Rio Tarumã Mirim; Figure 1a). They replaced nonflooded terra firme forests that previously occupied the area. Intermittent dry spells during high sea level periods may have caused

Figure 1 Postulated formations and shifts of black-water inundation forests along main rivers and affluents of Central Amazoni within the past 100,000 years due to changes in sea level and climate. (See text for further explanation.) Modified from Adis J (1984) "Seasonal igapó"-forests of Central Amazonian black-water rivers and their terrestrial arthropod fauna. In: Sioli H (ed.) *The Amazon. Limnology and Landscape Ecology of a Mighty Tropical River and Its Basin. Monographiae Biologicae*, pp. 245–268. Dordrecht: Junk.

formation of savanna and nonflooded terra firme forest refugia (Figure 1b), as postulated by Haffer. During low sea level periods, annual inundation occurred only along main rivers (e.g., the Rio Negro); this has been the case for at least 1 My, probably including all glacial advances of the Pleistocene and perhaps even since the Andes took their present configuration. Nonflooded vegetation on terra firme ("uplands") spread extensively, forcing igapó forests along affluents to retreat to main rivers (Figure 1c). Intermittent dry periods, according to Haffer, again caused savanna formation with possible nonflooded forest refugia on terra firme and "igapó forest refuges" (Figure 1d).

Flood cycles have a dramatic impact on inundation forest faunas. This is especially important when two kinds of flooding patterns manifest themselves through time. In the greater region of Amazonia, there could have been periods favoring lakeshore species, then inundation forest species, and then riparian species (for discussion of carabid beetles, see Erwin and Adis as cited in Prance, 1982). Large water bodies and drying affluents, with possibly additional regression of nonflooded forests on terra firme in both cases, cause interruption and isolation of igapó forests. Species vagility then seems to become a crucial factor in sorting out and isolating gene pools. Thus, small barriers may be highly disruptive to populations of individuals with low vagility, particularly nonflying soil arthropods. Supposing that intense competition and predation promote rapid speciation (especially in igapó forests, in which flooding mixes terrestrial and canopy biotas during half the year) and that the isolation of igapó forests is sufficiently long for rapidly evolving species, this model represents another key to Amazonian species richness. In fact, recent data indicate that (i) igapó forests retain many endemic species; (ii) the fauna of igapó forests is different in composition and activity patterns when compared with that of adjacent nonflooded terra firme forests; and (iii) in igapó forests across the Rio Negro and its tributaries, taxonomically different subspecies and species are found.

A third theory considers the high plant and animal diversity of Amazonian nonflooded terra firme to be a response to extremely low nutrient concentrations in geochemically impoverished ecosystems (Fittkau, 1973; Klinge, 1973). Species richness and simultaneously occurring high diversity of moist tropical ecosystems do not reflect high nutrient supply but rather a mode of adaptation to continuous restriction of nutrients or food substances under otherwise permanently favorable living conditions. Plants and animals are assumed to act as highly efficient "nutrient traps." During evolution of multiple life forms, shortages must have been of significant importance at all times.

A model group supporting this theory are the carabid communities on fig fruit falls. Paarmann and Adis sampled 8962 beetles on 65 fruit falls from 10 fig species between 1991 and 1996 in a nonflooded terra firme forest (Reserva Ducke) near Manaus. Eight of the 36 species collected represented the spermatophagous genus *Notiobia*, which accounted for 92% of all carabid beetles obtained. Only one *Notiobia* species was dominant. The abundance distribution of the eight *Notiobia* species was very similar on fruit falls of the two most common fig species as well as on fruit falls of the remaining fig species. The dominance structure varied considerably between

individual fruit falls. Also, the abundance distribution changed during the course of a single fruit fall. Only two of the eight *Notiobia* species were found to be specialized fig seed feeders, able to reproduce only on fig fruit falls (Vanicek *et al.*, 1994). The remaining six species of this genus use fig fruit falls as stepping stones between fruit falls of their host trees, which are separated by time and space.

Another theory for the high within-community diversity of tropical arthropods is that continuous stochastic local disturbances in nature are assumed to prevent the achievement of any long-term equilibrium (climax) state. These so-called stochastic nonequilibrium models assume that the presence of a species at a vacant site is important. This may represent an advantage against all species that arrive later. Niche overlaps are assumed to be very common within species-rich communities. As a result, neither successional nor a climax community can emerge. This is in contrast to the so-called deterministic equilibrium models, which are based on the ecological niche. Each organism maintains a defined position in its environment and, driven by competition, the system goes through defined successional stages and a structurally predictable climax equilibrium results (Linsenmair, 1990).

Examples that clearly support one or the other mechanism are not available for Amazonian arthropods. For example, concerning the diversity of the seed-feeding ground beetle community of the genus *Notiobia*, they are specialized on certain seeds as food for a successful larval development (deterministic process) and yet the nonfig seed specialists consume fig seeds to survive periods of food shortage. The necessity to do so limits the tendency to specialize. If stochastic processes do play a role in maintaining the diversity of the seed-feeding *Notiobia* species, this role is probably less important. Thus, they are "chance specialists" adapted to the unpredictability of fruit falls. The fig seed specialists belong to the "touring group," moving from one fig fruit fall to the next, depending on a sufficient density and an annually equal distribution. The aseasonal fruiting of figs is caused by their pollination biology.

Biotope and Habitat Specificity of Species

Conservation or sustainable use of Amazonian ecosystems demand information on biodiversity. Owing to the lack of basic comparative data on arthropods, recent recommendations mostly relate to the high diversity and rarity of species found in certain regions, which are called areas of "high biological value" (Anonymous, 1991; Dinerstein *et al.*, 1995; Kress *et al.*, 1998), rather than to specific indicator species of biotopes and/or habitats revealing endemism and possible centers of radiation. Two long-term studies on pseudoscorpions and tiger beetles demonstrate the validity for such information.

Pseudoscorpions were studied intensively in Central Amazonian biotopes between 1975 and 1990. The 35,000 specimens collected represented 26 genera and 60 species (Adis and Mahnert, 1990). Of these, 29 species (48%) occurred exclusively in nonflooded terra firme forests and 25 species (42%) were restricted to floodplain forests. Species from terra firme forests were more terricolous, with 69%

Source: Modified from Adis J, Paarmann W, Amorim MA, Arndt E, and da Fonseca CRV (1998b) On occurrence, habitat specificity and natural history of adult tiger beetles (Coleoptera: Carabidae: Cicindelinae) near Manaus, Central Amazonia, and key to the larvae of tiger beetle genera. *Acta Amazon* 28(3): 331–344.

living in litter and soil. Species from floodplain forests were predominantly arboricolous, with 88% living in the trunk and/or canopy region. Differences in habitat selection are attributed to the impact of the flood pulse in Amazonian floodplains, that is, long-term inundation of 5–7 months' duration. Only 11 species were found in forests inundated by white-water (Rio Solimões-Amazonas) compared with 20 species found in black-water forests (Rio Negro). This is attributed to the differences observed between biotopes (flora and soil structure) as well as between the two river systems (current and sediment load; Adis as cited in Junk, 1997).

Databases such as these help to answer general questions about specific biotopes. For example, the terricolous pseudoscorpions of terra firme forests on white sand soil in Central Amazonia (called campinarana) represent the species spectrum of primary terra firme forests on yellow latosol and show no endemic species (Adis and Mahnert, 1993). This reinforces the geological results that indicate that campinarana does not represent forests along former riverbeds which have dried up, as previously suggested, but rather the final stage of podzolization (i.e., the transformation of clayey latosols to white sand podzols by long-term weathering and leaching processes).

Of the 24 species of tiger beetles (Carabidae: Cicindelinae) studied between 1991 and 1998 in the Manaus area (Table 2), 15 were found in nonflooded terra firme areas. Of these, seven species lived in forests. Five of them, being diurnal, inhabited the floor (Figure 2: CVA, OCA, OLU, ONI, and PLA), and two species were canopy dwellers (CAS and CFO). Eight species, one nocturnal (MBI) and seven diurnal (ASE, BAR, BPR, CMO, OCH, CAS, OMA, and PVE), lived in open areas. Three of these were found on mostly bare latosol (BAR, OCH, and

PVE). The other five species occurred on mostly bare white sand (ASE, BPR, CAR, CMO, and MBI). The species assemblage in open areas indicated an impact by human intervention: *Pentacomia ventralis* (PVE) is known as a species that inhabits extensive cleared forest sites and *Odontocheila margineguttata* (OMA) occurs in secondary forests. Another nine tiger beetle species were recorded from white-water floodplains (várzea; Table 2). Of these, three diurnal species inhabited inundation forests (Figure 3: OC, PE, and PL). Six species, two diurnal (CS and PC) and four nocturnal (MA, MK, MP, and MS), lived in open areas. Four were found on bare beaches (CS, PC, MP, and MS). The other two species (MA and MK) inhabited grass-grown areas behind the beaches which were mainly composed of annual and perannual aquatic grasses. Only one species, *P. lacordairei*, occurred in the forests of both nonflooded terra firme and floodplains (Table 2).

Data clearly show the biotope and habitat specificity of these tiger beetle assemblages. Moreover, the life cycle of species on nonflooded terra firme differed greatly from those inhabiting floodplains, which indicates a high adaptation to the respective biotope and habitat. Data such as these might also help to elucidate questions of general interest. For example, the dichotomy of forest or open-habitat assemblages might be important for understanding tiger beetle distribution in Amazonia. Similar patterns were reported by Heyer for frogs east of the Andes (Vanzolini and Heyer, 1988). Data also support the potential use of tiger beetles as bioindicators for monitoring the degradation and regeneration of Amazonian forests. In Venezuela, forest-floor species assemblages changed significantly with the degree of forest disturbance, and each stage of disturbance was characterized by a particular subset of species (Rodríguez *et al.*, 1998).

Morphological Species

In millipedes, taxonomy is mainly based on the structure of genitalia in males, the gonopods. However, in the process of adaptation to new environments, “pioneers” apparently change their external structure more quickly than their gonopods, which results in difficulties in defining species. According to Hoffman (1990), the diversification of the external body form with little modification of gonopod structures in the order Polydesmida seems to be associated with those taxa (usually genera) that seem to have recently occupied a new area or biotope independently of close relatives and are indulging in a burst of adaptive radiation unimpeded by sibling competition. It is presumed that after an initial period of great diversification some selection of successful lineages would occur. During this time, body form types, stabilized by adaptational factors, would tend to remain constant. The generic variability, however, might be expressed much more rapidly in structures such as genitalia, which are less directly influenced by environmental constraints. Thus, a period would ensue in which these species groups (or genera) would consist of species readily distinguishable by highly

distinctive gonopods. Such a stasis would endure for a long time unless it were again possible for a fragment of a group (probably migrant populations of one or two species) to escape into a new area or new ecological niche and begin the cycle anew. This situation seems to be different from the punctual evolution of new clades in that two basically different character systems alternate in phase with the chronological status of the organisms in “new” and “old” territory and thus underscore the principle that phylogeny cannot be adequately interpreted outside the context of biogeography.

New insights derived from studies on the Neotropical genus *Pycnotropis* support these postulations. Among the 26 species known, only three are restricted to Amazonian white- and mixed-water inundation forests, whereas the remainder are found in nonflooded terra firme forests. Biogeographically, the history of *Pycnotropis* can be viewed as one implying the origins in the western Andes, the postulated center of origin (and radiation) of the entire subfamily Amphininae, with subsequent waves of downstream dispersal throughout the Amazon Basin. The present-day distribution of *Pycnotropis* is the result of numerous, apparently ongoing vicariance events involving repeated gene flows downstream of the Amazon and its tributaries (radiation corridors) from source areas, with colonization and recolonization of inundation forests and/or non-flooded terra firme habitats. The genus is still in a stage of very active speciation because at least some of its species display pronounced variation in both external and gonopod characters. This is supported by preliminary tests concerning genetic variation in *Pycnotropis tida*, a species that has been described twice due to variation in morphological characters. The pattern of a somewhat “unsettled” speciation process seems to contrast the one observed in the chelodesmid genus *Camptomorpha*, which likewise is species-rich in the Andes and abundantly represented in the Amazon Basin. It is, however, a good example of a taxon in the “stable body-variable gonopod” stage, with each species being distinct morphologically (Golovatch *et al.*, 1998).

Genetical Species

Comparative phenological studies on arthropod species that inhabit both floodplain and nonflooded terra firme forests in Central Amazonia suggested an uni- or bivoltine life cycle of populations in annually inundated forests and a plurivoltine mode of life of populations in terra firme forests. Representatives of both populations were morphologically alike; hence, they represented the same species (e.g., in Pseudoscorpiones, Diplopoda, Symphyla, and Archaeognatha).

In the case of *N. scandens*, a member of the Meinertellidae (Archaeognatha, Insecta), the two populations in terra firme and floodplain forests were first postulated to be “biotope-specific races.” Morphological characters that would justify separation into two species could not be found by the taxonomist, at least with traditional research methods. However, protein analyses by means of electrophoresis (testing 15 enzymes) revealed that there is no gene flow between populations from floodplain and terra firme forest types, even when they are only 50 m distant from each other. Thus, this “species” was proposed to represent two different species based on ecophenological and genetic characteristics. Without this

Figure 3 Species of tiger beetles (Carabidae: Cicindelinae) found on Ilha de Marchantaria, the first island in the Rio Solimões near Manaus, Central Amazonia. Reproduced from Adis J, Paarmann W, Amorim MA, Arndt E, and da Fonseca CRV (1998b) On occurrence, habitat specificity and natural history of adult tiger beetles (Coleoptera: Carabidae: Cicindelinae) near Manaus, Central Amazonia, and key to the larvae of tiger beetle genera. *Acta Amazon* 28(3): 331–344.

genetical background, problems arise if the two genetical species occur sympatrically because, due to the intermixture of data, the ecophenological differences are hardly or not at all recognizable. This was the case in a mixed-water inundation forest near Manaus (Wolf and Adis, 1992). Until now, culturing and breeding of Amazonian Meinertellidae was unsuccessful; thus, interbreeding experiments could not be performed.

The polydesmidan millipede *P. tida* (see Morphological Species) represents a second example. In the Manaus area, populations that inhabit secondary terra firme forests breed throughout the year, whereas populations of white- and mixed-water inundation forests show a defined, univoltine reproduction during the nonaquatic phase (Vohland and Adis, 1999). The genetic data were obtained from allozyme analyses (testing 14 enzymes by electrophoresis) and from a specific satellite DNA. In this case, results suggested that individuals from the two biotopes represented populations of the same species, although genotypic structures among and within local populations indicated processes of ongoing genetic differentiation (Bachmann *et al.*, 1998). A successful interbreeding thereafter reinforced the genetical results.

For taxonomists, the use of genetic techniques and the consideration of ecological as well as ethological data represent the final, although mandatory, stage of analysis in systematic biology. In the case of Amazonian Pseudoscorpiones and Symphyla, both genetic and breeding exercises have not been successful.

Prospects

Amazonian terrestrial arthropods are special: they have adapted in some way to their environment. Only detailed

studies at the species level will reveal the “strategies” which have evolved. For example, there are (i) grasshoppers on aquatic macrophytes in the Rio Amazonas with spiny front legs, like mantids, that follow their prey into tree canopies during high water (*Phlugis teres*, Tettigoniidae); (ii) a small, flood-resistant “terrestrial” millipede which lives up to 11 months submerged in inundation forests along the Rio Negro, breathing under water by means of a plastron and feeding on algae (*Gonographis adisi*, Pyrgodesmidae); and (iii) larvae of a carabid beetle (normally a predaceous taxon) which accomplish their development feeding on fig seeds (*N. flavicinctus*) but apparently depend on larvae of their sister species (*N. pseudolimnipennis*) which are able to open the seed shells with their morphologically larger mandibles. Some insights into this fascinating world have been achieved since Bates voyages on the “River Amazons.” However, it took about 150 years to adopt his suggestion to study 1 acre of rain forest in more detail. Two approaches are currently being taken. One is to develop an All-Taxa-Biodiversity-Inventory and the other to develop an All-Biota-Taxon-Inventory (Platnick, 1999). Both enterprises require an intensified training of tropical taxonomists and ecoentomologists.

Glossary

Fauna The animal species living in a defined area.

Leaf beetles Members of the family Chrysomelidae.

Phytophagous Feeding on plants; also, herbivorous.

Weevils Members of the beetle family Curculionidae.

Introduction

In terms of numbers of species, arthropods are the largest phylum of living organisms, insects are the largest group within the arthropods, and beetles are the largest order among the insects. Beetles presently comprise about a quarter of all described, extant organisms. This numerical dominance led the British biologist J. B. Haldane to answer the question of what one might learn about the mind of the Creator from a study of his creation with the famous reply: “An inordinate fondness for beetles.”

In 1982, T. L. Erwin used samples of beetles to estimate that the number of species of living organisms may be 30 million or more. The ensuing controversy (especially Stork, 1988) rekindled interest in the more general question of the magnitude of global biodiversity (May, 1988) and how to measure it. These discussions did not question the usual assumption that beetles represent the largest part of global biodiversity, although mites and nematodes may in fact be more diverse than beetles. More recently and narrowly, a proposal to “explain” the diversity of beetles has itself engendered controversy. Both questions are reviewed here.

What Beetles Are?

The order Coleoptera is usually divided into four suborders and 160–170 families depending on the author. The suborders Archostemata and Myxophaga each consist of four families and fewer than 100 extant species. The Adephaga includes about a dozen families, with most of the species in the large family of ground beetles Carabidae. All other beetles—150 families and 90% of the 340,000 species—are classified as Polyphaga. Somewhat more than two-thirds of the species belong to the eight largest families discussed here, each with more than 10,000 species, but there are 30 other families that have between 1000 and 10,000 species (Table 1). The most thorough review of the biology of members of the order is found in Crowson (1981).

Because they are well sclerotized, there is a good fossil record for beetles. Beetle-like insects first appeared in the Lower Permian, modern families are known from the Cretaceous, and extant genera date from the Oligocene and Miocene. Ecologically, beetles are the most diverse order of insects, which is a primary factor in their great species richness. There

are large families of beetles that live in fresh-water habitats, that are predaceous and parasitic, and that feed on fungi and detritus, but the largest proportion of described species feed in some way on plants. Among these phytophagous beetles, the largest number of species are wood-borers; a much smaller number feed directly on leaves, and some feed on seeds.

Diversity—How Many Beetles Are There?

Gaston (1991) has reviewed current estimates of the number of insect species described, favoring those of J. F. Lawrence for beetles. Lawrence (1982) put the numbers of beetles at 340,500 species divided into about 25,000 genera and placed in 169 families. His estimate of the number of species falls in the middle of estimates (290,000–370,000) cited by Gaston, and roughly equal to the sum of the number of species in the three next largest insect orders (Diptera, 98,000–120,000 species; Lepidoptera, 112,000–165,000 species; Hymenoptera, 100,000–130,000 species). Estimates of the total number of living species, described and undescribed, are difficult to relate to the number of described species for two major reasons. First, most taxonomic research has been carried out in the north temperate regions of the world on organisms that live there, whereas most insect species are tropical. Second, different groups of insects have received differential amounts of study from scientists, both within the beetles and between beetles and the other insect orders. This article briefly reviews what is known about the major beetle families, considers explanations for the success of the order, reviews a few ecological and biogeographic patterns in beetle diversity, and then discusses the problems in estimating what we don’t yet know about beetle diversity.

As stated earlier, eight families of beetles currently account for more than half of all beetle species. However, unequal efforts in the collection and study of different groups very likely mean that the relative sizes of these families will change when the less well studied taxa become better known. Some of the better-studied groups have already begun to be used to test hypotheses of mechanisms that might promote or maintain beetle diversity; for example, whether speciation in plant-feeding beetles parallels speciation in their hosts. The eight major families are considered in order of their traditional phylogenetic placement.

Table 1 Diets and numbers of species and genera of the larger families of beetles (more than 1000 species)^a

^bA = aquatic, D = detritus, F = fungi, L = leaves, P = phytophagous, S = seeds, W = wood-boring.

Carabidae

The ground beetles (30,000 described species, including the tiger beetles, sometimes placed in the separate family Cicindelidae) are primarily predatory. Although some carabid groups are very rich in tropical regions, others do not show as great an increase in diversity there as do other beetles. Despite the vernacular family name, tropical forms are commonly arboreal. Tiger beetles are well studied taxonomically, have been used to test ecological and evolutionary hypotheses, and have been suggested as indicator species for biodiversity studies (Pearson and Cassola, 1992).

Staphylinidae

The rove beetles (30,000 species) are both numerous in species and diverse ecologically, including predatory, fungus, and detritus feeders. The staphylinids are the least well known family of beetles, with perhaps only 10% of extant species described, and may eventually prove to be the largest family. They are abundant in canopy fogging samples in tropical regions.

Scarabaeidae

The scarabs (25,000 species) are primarily phytophagous, but with one group well known as dung beetles. Because they are popular with collectors, they are among the best known of the beetle groups. The actual number of extant species is unlikely to be more than twice as many as those already described.

Buprestidae

The jewel beetles (15,000 species) include a majority of wood-boring species and several groups of leaf-miners. Although larger species are popular with collectors, the smaller species are primarily subtropical and tropical and very poorly known. The genus *Agrilus* may be the largest genus of living organisms with 2000 described species and many more undescribed—there are nearly 350 undescribed species among more than 600 known from México alone. At La Selva Biological Station in Costa Rica, 24 of 29 *Agrilus* (83%) are undescribed; of 206 Buprestidae, 147 (71%) are leaf-miners and 62% are undescribed. The family should more than double in size when completely known.

Tenebrionidae

The darkling beetles (18,000 species) are phytophagous and have been relatively popular and well studied in temperate and subtropical regions. I have seen no discussion of its current taxonomic status or estimates of undescribed species.

Cerambycidae

The long-horned beetles (35,000 species) are wood-borers, very popular among collectors, and well studied. Of 274 species collected at La Selva, only 23 (8%) are undescribed, although another 28 (10%) are still undetermined. It is possible that the number of species will double when the rich

South American fauna is more fully known. This and the following two families constitute the Phytophaga and are the largest beetle families in described species.

Chrysomelidae

The leaf beetles (35,000 species) are by far the largest group of beetles that primarily feed on the leaves of plants. Some groups within the family are relatively well studied, even within tropical areas (Cassidinae), whereas others are not (Alticinae). Members of the family are common in canopy samples and have been shown to speciate in parallel with their plant hosts. The success of beetles overall has been attributed to the success of this and the other two families in the Phytophaga. When the total chrysomelid fauna is known, it will probably double the number of currently known species.

Curculionidae

The weevils (50,000 species) are the largest family of living organisms. Although they are primarily phytophagous and associated with angiosperm plants in a variety of ways, many (and perhaps most) are wood-borers (many Cryptorhynchini, Molytini, and Zygopini) rather than leaf-eaters, in some cases cultivating fungi in their tunnels (Platypodinae and some Scolytinae). The great majority of weevils are endophytic; the few that feed directly on leaves often do so as leaf-miners. Sampling at tropical localities has yielded large numbers of weevils. At Barro Colorado Island in Panamá, three years of light trapping (Wolda *et al.*, 1998) yielded 1240 species of Curculionoidea (excluding Platypodinae and Scolytinae, but including about 200 species from four other families). Sampling at La Selva has collected well over a thousand species of weevils, including 504 in the largest tribe, Zygopini, of which 425 (84%) are undescribed. The number of species is probably two to three times those presently known.

Explanations for the Species Richness of Beetles

Farrell (1998) recently claimed to have verified an earlier proposal that the great species richness of Coleoptera is due to the association of the largest lineages within the Phytophaga (Cerambycidae, Chrysomelidae, Curculionidae) with angiosperm plants. Indeed, beetles feed on angiosperms in a number of ways. The narrowest form of phytophagy is to feed on leaves (foliivory), but very few beetles do that, primarily Chrysomelidae and leaf-miners in several families. As foliivores, the Lepidoptera are much more successful (most of 140,000 species). A few phytophagous beetles feed on seeds (Bruchidae, some Curculionidae), but most are wood-borers (Buprestidae, Cerambycidae, many Curculionidae). Perhaps more than qualities of the host itself, it is the ability of beetles to feed endophagously in wood and other plant tissues that makes them so successful. Anderson (1995) has attributed the success of weevils, the most species-rich lineage, to the evolution of the rostrum as an aid to oviposition in plant tissues. It is more difficult for Diptera and Lepidoptera to feed

endophagously because adults lack chewing mouth-parts with which to exit plant tissues.

Another problem with the Farrell hypothesis is that even if the Phytophaga were removed from the beetles, the remaining taxa are still twice as numerous as any other insect order. If the Staphylinidae are as species rich as has been suggested (300,000 species), that family alone would be more than twice as large as the currently known Phytophaga and about the same size as estimates of total Phytophaga. The success of beetles is almost certainly due to their use of so many major resources, not just their intensive use of one of them. Of the 8 largest beetle families, the Carabidae are primarily predaceous and the Staphylinidae are partly or largely so; 10 of the other 30 families with more than 1000 species are also primarily predaceous. Five of the larger families and some Staphylinidae feed on fungi, which is another major adaptive zone for beetles. Aquatic habitats are used by two large families of beetles and only by Diptera among the other three major orders.

Ecological samples of canopy insects, although dominated by phytophages, include significant portions of species of other feeding types. If only half of all beetle species feed on angiosperm plants, it could be argued that beetles are in fact *less* successful than expected, for the reason that angiosperms constitute a much larger resource in terms of productivity and biomass than the other trophic levels in which beetles feed with equal success. In sum, there is no single simple explanation for the great diversity of beetles. Although association with angiosperms has obviously been a major factor in the diversification of beetles, it has been so in a very complex way that may be due less to the plants as a resource and more to the features of the beetles ("preadaptations") that allowed them to use the plants endophagously.

Taxonomic and Ecological Patterns

Most large taxa have greater numbers of species in tropical regions than in temperate ones, and that pattern is likely to hold for families of beetles. Increase in species numbers at lower latitudes is not usually a matter of uniform increases in all genera within the taxon, but rather of changes in dominance among taxa. For example, in the Buprestidae, wood-boring genera dominate in temperate and subtropical regions both north and south of the equator, but leaf-mining genera dominate near the equator. Among the leaf-miners, the genera *Brachys* and *Taphrocera* dominate in temperate and subtropical regions, but the genera *Hylaeogena*, *Leiopleura*, and *Pachyschelus* dominate near the equator. In the Chrysomelidae, the subfamily Clytrinae has a peak in species richness in the subtropics, as does the zygotine weevil genus *Cylindrocopturus*.

More complex relationships between species diversity and ecological diversity are suggested by some data. The wood-boring Cerambycidae increase in absolute species richness as one moves towards the tropics, but F. T. Hovore (unpublished data) has found that species richness relative to potential woody plant host species diversity actually decreases at lower latitudes because of a greater increase in the number of woody plant taxa (Figure 1). This is not unexpected in that many tropical plant species are rare, and Southwood and others have

Figure 1 Diversity of the beetle family Cerambycidae at several sites as a function of latitude. Number of species is given on the left axis (squares)—the number increases from the temperate zone to the tropics. Relative diversity is shown on the right axis, expressed as the number of species of beetles compared to the number of species of potential woody plant hosts (circles)—the number of beetle species increases less rapidly than the number of potential hosts. (Data from F. T. Hovore, unpublished.)

shown that rarer plants have fewer host-specific herbivores than do more common plants. In the tropical Cerambycidae, many of the species are associated with a few larger, more abundant host plant genera such as *Inga* and *Ficus*, and host generalists may be common.

Mimicry is more common in tropical beetle species than in temperate members of the same taxon. The proportion of species participating in mimicry complexes has been shown to increase with decreasing latitude in *Agrilus* (Buprestidae) mimicking the ant genus *Zacryptocerus* and in zygotine weevils mimicking a variety of models. On the other hand, mimicry of and by clytrine chrysomelids is most frequent in the subtropical regions of México, where the clytrines are most species rich.

How Much Don't We Know?—Local Faunas

Estimates of how many beetle species exist in various families and the contribution of beetles to global biodiversity should be placed in the context of our extensive, basic ignorance of the ecology and distribution of beetles at local and regional scales. Except perhaps for England, there is no place on earth of any size and ecological diversity where one can make a complete list of all beetle species. In areas where checklists have been attempted, the larval biology and population ecology of many or most species are completely unknown. Lists of described species are incomplete, and a significant number of species are undescribed in all but the most popularly collected taxa. A few small taxa have been surveyed both intensively at a few sites and more or less extensively at scattered sites (Pearson and Cassola, 1992). In general, recent extrapolations to global diversity estimates have been made from samples of local faunas.

Beetles occupy such a wide variety of ecological roles in communities that no single method of sampling is adequate, even when the taxonomic scope of the beetles studied is relatively narrow. In recent years, Malaise trapping and canopy fogging have become popular, but flight intercept traps, sweep

netting, blacklighting, Berlese sampling, pitfall traps, baiting, beating, systematic rearing, and other methods have been used as well. Malaise traps sample active, flying insects (e.g., Mordellidae), and beetles in Malaise samples have been used as indicators of specific habitats. Light trapping (Wolda *et al.*, 1998) is successful in sampling cryptorhynchine and molytine weevils, but is poor for diurnally active zygotines and baridines. Canopy fogging has been widely used in recent years to sample beetle faunas.

Several major projects have attempted to inventory the arthropod faunas of single, diverse localities. The Arthropods of La Selva (ALAS) project in Costa Rica, for example, uses a combination of four standardized sampling techniques (Malaise trapping, canopy fogging, litter sampling, and light trapping), as well as group-specific collecting methods, to survey a variety of arthropods including several beetle groups. A similar variety of sampling techniques were employed in Sulawesi (Hammond, 1993). These and other such projects in tropical regions have been slow in producing more than partial faunal lists because of the massive taxonomic problems associated with rich tropical faunas that have been largely unstudied (see the following sections). The current ecological concept of metapopulations raises questions about the meaning of local faunas by suggesting that local diversity is a dynamic function of regional diversity. The idea that some “sink” populations are maintained by regular immigration from “source” populations elsewhere may explain anecdotes of the sudden and irregular appearance and disappearance of species of leaf-mining Buprestidae at La Selva in Costa Rica.

Estimating Diversity Globally

The problem of rare species has both ecological and taxonomic–evolutionary implications. Rare species are difficult to sample and difficult to interpret when they are sampled. Apparent rarity can be due to several factors, including methodological artifacts, disturbance by “tourists,” seasonal phenology, cyclic populations, or true biological rarity. Furthermore, small populations may be characteristic of tropical species. Three years of light trapping by Wolda at Barro Colorado Island, Panamá, yielded over 95,000 weevil specimens, but 28% of the 1239 species were represented by a single specimen. In smaller samples at six other localities in the same study, unique specimens represented 39–51% of the species. Canopy fogging samples show comparably high proportions of rare species. Reliable taxonomic decisions about what is or is not a valid biological species often require series of specimens to interpret variation; adequate series for studies are even more necessary when specimens from several localities are involved. Many described tropical species are known only from unique type specimens. The question of what is a species has been justifiably raised in discussions of biodiversity at regional and global geographic scales.

Erwin (1982) startled the scientific world by calculating that 1200 beetle species (955 counted, 206 weevils estimated, then “rounded up” to 1200) sampled from 19 individual trees of *Luehea seemannii* implied that there were 30 million species of insects worldwide. His extrapolation depended on three important quantities: his estimate of the proportion of

host-specific beetles, the fraction found exclusively in the canopy, and the assumption that all tree species have the same number of herbivores. The last of these is certainly not true—rare tree species have fewer host-specific insects (see earlier discussion).

Empirical studies that sample both the canopy and lower levels in the forest have not shown a large and/or distinct canopy fauna. Gaston (1991) interviewed taxonomic specialists of many insect taxa, including for beetles, and concluded that the proportions of undescribed species in tropical samples were high but not high enough to warrant an estimate of 30 million species (if 1 million species are known and 30 million exist, undescribed species would comprise 97% of samples).

Other means of estimating global species richness have been used. Rates of description of new species of beetles (“trend lines”) have been extrapolated to an asymptote, but this method incorrectly assumes constant levels of scientific study and publication. May (1988) compared observed with theoretical distributions of body size and abundance to estimate the numbers of undescribed species, primarily those in the smaller size classes. It is certainly true that larger organisms are more likely to be collected and described than are smaller organisms. In each of the other major orders of insects, it is the smaller species that are least well known: for Lepidoptera, it is the microlepidoptera; for Hymenoptera, the smaller parasitic wasps in the Chalcidoidea; for Diptera, the small Nematocera and Phoridae. In beetles, Gaston showed that larger beetles were described earlier and that the average size of the species being described decreases as one nears the present. Of the zygotine weevil species identified at La Selva, 57% of weevils larger than 4 mm in length are undescribed (88 measured), but 81% of those less than 4 mm are undescribed (146 measured). Methods of estimating unsampled species from theoretical abundance frequency distributions depend on the mode of the distributions being defined, which is not usually possible for tropical samples. It seems to be true for all estimates of global beetle or insect species numbers, regardless of the sampling method used, that what is not known is so large compared to what is known that a precise estimate is impossible.

What do We Know and How Likely are We to Ever Know?

Beetles are a very large group of organisms and are diverse both taxonomically and ecologically. The 169 families and 340,000 described species currently comprise somewhat less than half of all known insects and about a quarter of all living organisms. About 40 families of beetles have more than 1000 described species, and 8 families have more than 10,000 species. About half of all beetle species feed on plants, usually as endophages on woody or other support tissue, but there are a large number of predatory species, as well as lesser but significant numbers of fungivores, detritivores, and aquatic forms. This ecological diversity precludes simple explanations for the diversity of beetles. However, many beetle families show general patterns of distribution, for example, greater diversity in tropical latitudes and the greater importance there of antipredator defenses such as mimicry.

These crude generalizations aside, we actually know rather little about most beetles. Because of the popularity of certain beetle groups, the various families have been unequally studied. Parts or all of the families Carabidae, Scarabaeidae, Buprestidae, Tenebrionidae, and Cerambycidae have been relatively better studied, whereas the three largest families (Staphylinidae, Chrysomelidae, and Curculionidae) are the most poorly studied. Ironically, as we have become aware of the existence of large numbers of undescribed species by using new sampling methods in previously little-collected tropical areas, the number of professional taxonomists able to name and describe species has been declining. Many positions for taxonomists have been lost at most major museums, funding for taxonomic research has declined, and the trend in research has been toward genetic analyses for the purpose of elucidating phylogenetic relationships rather than describing species. Money has become available for sampling and conducting species inventories, especially in threatened tropical areas, but not for processing and studying the material collected beyond simple sorting of a few target or focal taxa and counting of their putative “morphospecies.” May (1988) showed that, although beetles are the largest group of organisms, they have the lowest rate of publications per described species of all organisms except nematodes. He expressed amazement that there is, in fact, no complete worldwide catalog of insects that would allow one to know how many are actually described (hence the varying “estimates” of even the numbers of described species).

At the level of local or regional faunas, there are few sites outside of Western Europe where beetle faunas are more than partially known. The richest areas—the tropics, and especially the Neotropics—are virtually unknown faunistically outside of samples taken at a few widely scattered sites. Many large regions of the tropics have never been significantly collected for any beetle groups. Costa Rica’s National Biodiversity Institute (INBio), including the ALAS project at La Selva, has made the most extensive collections toward a regional fauna of any tropical country, but their collections favor larger species, are only partially mounted and sorted, and are only beginning to be studied. Overall, then, there is no good estimate of global species richness for beetles and few data on which to base such an estimate.

As the magnitude of how much we still don’t know becomes clearer, there are serious questions about whether we will ever understand the extent of beetle diversity in light of the declining number of taxonomically trained scientists and the possibility that many species will go extinct because of human activities before they are ever collected or studied. The decline in the number of scientists who are able or willing to

describe species is unlikely to be halted. Furthermore, widespread beetle extinction over the next century is especially likely in the face of the accelerating environmental destruction of the richest sites in the tropics to accommodate growing human populations and, even more significantly, to maintain Western European and North American standards of living. Unfortunately, it is a safe guess that we will never completely know how many beetles there were.

Acknowledgments

I thank F. T. Hovore for reviewing this manuscript and allowing me to publish some of his data. I have been supported by the Research Committee of the UCLA Academic Senate and by grants in support of the ALAS Project (National Science Foundation Grants BSR 9025024, DEB 9401069, and DEB 9706976).

Glossary

Aposematic Describing an organism that is rendered less susceptible to predation by advertising its obvious unpalatability.

Batesian mimicry A form of mimicry in which the target organism is rendered less susceptible to predation by its resemblance in morphology or coloration to a different species that is unpalatable.

Cryptic Describing an organism that is concealed or obscured by the similarity of its appearance to the surrounding environment.

Müllerian mimicry A form of mimicry in which two or more unpalatable species resemble each other, with the effect that predators are more likely to avoid any species with this appearance.

Myrmecophily Ability to form symbiotic associations with ants.

Vibratory papillae Mobile, grooved, rod-like appendages arising from the distal edge of the first thoracic segment, used for communicating.

Overview of Butterfly Taxonomic Diversity

Although butterflies may be the best known group of insects, our understanding of their taxonomic diversity has two fundamental weaknesses. The first regards the recent decline of professional butterfly taxonomists and species level revisions in the past 50 years. This requires most species diversity estimates (from family to genus) to be derived from a literature that is out-of-date. The second is that the number of families and subfamilies of butterflies varies among classifications because, despite current interest in phylogenetic systematic methods and analyses, the relationships within the major groups are unresolved, particularly within Nymphalidae and Lycaenidae. Such is the state of butterfly taxonomy. Nevertheless, the “true” butterflies (superfamily Papilionoidea) may be placed conservatively into four families (Papilionidae, Pieridae, Nymphalidae, and Lycaenidae) that together include between 12,900 and 15,819 species. One useful framework for organizing butterfly taxonomic diversity is P. R. Ackery's (1984) synthesis of butterfly classification, which forms the basis of the following synopsis:

Family Papilionidae (Swallowtails, **Figure 1**): a group of 500–600 species in three subfamilies, distributed worldwide but with most species being tropical; adults medium to large sized, both sexes have six walking legs bearing nonbifid tarsal claws; most are brightly colored, may be Batesian or Müllerian mimics, all feed on flower nectar, and males drink at wet soil (**Figure 1**); caterpillars are herbivores, body smooth without hardened spines, and possess extrusible glands (osmeteria) that are unique among butterflies; pupa typically with a silk girdle at third thoracic segment.

Subfamily Baroniinae: one species (*Baronia brevicornis*) endemic to Mexico; caterpillars unique among the family by feeding on Fabaceae.

Subfamily Parnassinae: 40–50 species, mainly in north temperate mountains; host plant families include Crassulaceae, Fumariaceae, and Zygophyllaceae.

Subfamily Papilioninae (**Figure 1**): more than 500 species placed into three or more tribes; distributed worldwide; most species are tropical. Many species with long hindwing tails; many with sexes strongly dimorphic; many involved in mimicry; species range from palatable mimics (*Papilio* and *Eurytides*) to unpalatable models (*Parides*, *Pachliopta*, and *Troides*), and some are among the largest butterflies (*Trogonoptera* and *Ornithoptera*); host plant families include Annonaceae, Apiaceae, Aristolochiaceae, Fumariaceae, Hernandiaceae, Lauraceae, Magnoliaceae, Rosaceae, and Rutaceae.

Family Pieridae (whites, sulphurs, jezebels, cabbage butterflies; **Figure 1**): a group of more than 1100 species in four subfamilies; adults small to medium-sized, both sexes have six walking legs and distinctly bifid claws; most species are white or yellow or orange (or combinations thereof) derived from pterin pigments, some with red and black patterning; adults feed on flower nectar (**Figure 1**), and males visit wet soil; caterpillars are herbivores, body smooth without hardened spines, often covered in granulations; pupa suspended at 45° angle from substrate with silk girdle at the first abdominal segment.

Subfamily Pseudopontinae: one species (*Pseudopontia paradoxa*) endemic to West Africa; early stage biology unknown.

Subfamily Dismorphiinae: approximately 100 species, nearly all Neotropical. Most *Dismorphia* (**Figure 1**) are astonishingly precise mimics of certain aposematic Nymphalidae (*Heliconius*, *Mechanitis*, and *Oleria*), and represent the original example from which Batesian mimicry theory was derived; host plants are in the Fabaceae.

Subfamily Pierinae (whites, jezebel, and cabbage butterflies): approximately 700 mostly tropical species, especially in Africa and Asia; some species have spectacularly bright, contrasting colors of white, red, and black (e.g., *Delias*, *Mylothris*, *Pereute*, and allies) suggesting unpalatability and warning coloration; some groups with dimorphic sexes in which females resemble unpalatable nymphalids and papilionids; some species undergo spectacular mass migrations (e.g., *Ascia*,

Figure 1 Adult butterflies. Clockwise from upper left: (a) newly eclosed male *Eurytides protesilaus* (Papilionidae) drinking from wet soil; (b) male *Theritas* nr. *hemon* (Lycaenidae: Theclinae) perching on a leaf; (c) male *Dismorphia amphiona* (Pieridae: Dismorphinae) visiting flowers; (d) female *Mechanitis isthmia* (Nymphalidae: Ithomiinae) ovipositing a cluster of eggs. (All photos copyright P. J. DeVries.)

Appias, and *Belenois*), and a few species are crop pests (*Pieris*); host plant families include Capparidaceae, Brassicaceae, Santalaceae, and Loranthaceae.

Subfamily Coliadinae (sulphurs): 400–600 species well represented in temperate and subtropical regions; generally yellow or white with short, thickly scaled antennae; common in open areas, some migrate in large numbers and have been recorded out at sea far from land (*Colias*, *Phoebis*, *Catopsilia*, *Aphrissa*, and *Eurema*); many species with patterns visible only in the ultraviolet.

Family *Lycaenidae* (hairstreaks, blues, coppers, and metal marks; **Figure 1**): a group of 6000–6500 mostly tropical species in 10 subfamilies (the total number may change with future study), and accounts for nearly 50% of all butterflies; most species are small to very small, both sexes have six walking legs (except Riodininae), and frequently with alternating black and white bands on the antennae; the group displays a tremendous diversity of form, color, and life histories; adults feed on flower nectar, fruits, carrion, and honeydew, and a few species do not feed as adults; some African and Southeast Asian groups are involved in mimicry complexes; caterpillars most often slug-like, without hard spines or projections, but the Riodininae shows an extensive variety of form; as a group, lycaenids have the widest diet breadth of all butterflies, and depending on the group caterpillars may feed on plants, other insects, or insect secretions; many caterpillars form intimate and complex symbiotic

associations with ants and produce acoustical calls similar to ant calls, secretions that are harvested by ants, and chemicals that alter ant behaviors; pupae are typically round, seed-shaped, unadorned with projections, and may produce clicking or whirring sounds when stimulated.

Subfamily Riodininae (metalmarks): 1200–1400 species that are almost exclusively Neotropical; arguably the most diverse of all lycaenoid groups with respect to adult and larval forms, and they are often treated as a distinct family (Riodinidae) divided into five subfamilies; adults feed primarily on flower nectar, some drink at wet soil, others at carrion; overall their life histories are poorly known, but as a group riodinid caterpillars appear to be mainly herbivores (*Euselasia*, *Mesosemia*, *Ancyluris*, *Metacharis*, *Mesene*, *Symmachia*, *Emesis*, *Anteros*, and *Helicopsis*), with a few carnivorous species on Homoptera (*Alesa* and *Setabis*); about one-third of the riodinids form symbioses with ants and have vibratory papillae as sound producing organs (*Thisbe*, *Audre*, *Lemonias*, *Synargis*, *Nymphidium*, and *Setabis* (**Figure 2**)); riodinid myrmecophily is entirely Neotropical; host plant families include Araceae, Asteraceae, Bromeliaceae, Bombacaceae, Cecropiaceae, Clusiaceae, Dilleniaceae, Euphorbiaceae, Fabaceae, Lecythidaceae, Loranthaceae, Malpighiaceae, Marcantaceae, Melastomataceae, Myrtaceae, Orchidaceae, Rubiaceae, Sapindaceae, and Zingiberaceae plus mosses, liverworts, and lichens.

Lower left—detail of vibratory papilla. Lower right—head granulations at high magnification; (d) final instar caterpillar of *Thisbe irenea* (Lycaenidae: Riodininae) being tended by ants. (All photos copyright P. J. DeVries.)

Subfamily Styginae: one enigmatic species (*Styx infernalis*) that is endemic to the Peruvian high Andes; the early stage biology is unknown.

Subfamily Lipteninae: a small African group of 30–40 species; some are Batesian mimics of aposematic nymphalids (*Mimacraea* and *Ornipholidotos*); caterpillars feed on lichens and microscopic fungi (*Durbania* and *Deloneura*).

Subfamily Poritiinae: a small group restricted to the Oriental regions; caterpillars may be gregarious, feed on plants in the Fagaceae (*Poritia*), and may not associate with ants.

Subfamily Liphyrinae: a small group found in Africa, Australia, and Asia; adults have the proboscis partly or entirely atrophied; depending on the species, caterpillars feed entirely on insects (Homoptera) or on ant brood within ant nests (*Liphyra* and *Aslauga*).

Subfamily Miletinae: a moderate-sized group with most species in tropical Africa and the Orient and one in North America; caterpillars mainly feed on nymphs of Homoptera (*Feniseca*, *Spalgis*, and *Allotinus*), with a few species feeding on secretions of Homoptera (*Allotinus*) or ant regurgitations (*Thestor*); adults feed mainly on honeydew secretions of Homoptera.

Subfamily Curetinae: approximately 40 species restricted mainly to tropical Asia, all in the genus *Curetis*; caterpillars with tentacle organs as conspicuous, rigid cylindrical tubes; caterpillars feed on Fabaceae and have loose associations with ants.

Subfamily Theclinae (hairstreaks; **Figure 1**): this very large and diverse group is found worldwide, but most species are tropical; caterpillars are mainly herbivores, some carnivores on Homoptera, and many associate with ants, but the life histories of most species remain unknown; host plant families include Anacardiaceae, Annonaceae, Asteraceae, Bromeliaceae, Clusiaceae, Cycadaceae, Euphorbiaceae, Fabaceae, Fagaceae,

Geraniaceae, Lecythidaceae, Loranthaceae, Malpighiaceae, Malvaceae, Melastomataceae, Meliaceae, Myrtaceae, Oleaceae, Orchidaceae, Sapindaceae, Sapotaceae, Solanaceae, Sterculiaceae, Ulmaceae, and Verbenaceae.

Subfamily Lycaeninae (coppers): a group of 20–40 species found mainly in temperate regions, a few are tropical; caterpillars are herbivores on Polygonaceae, and some form loose associations with ants.

Subfamily Polyommatainae (blues): a large group with a worldwide distribution, most are pale, reflective blue above; caterpillars appear to always associate with ants, and their diets range from herbivores to carnivores, and some (*Maculinea*) feed on ant larvae and are clearly complex parasites and predators within ant nests; host plant families include Crasulaceae, Euphorbiaceae, Fabaceae, Lamiaceae, Myrsinaceae, Oxalidaceae, Primulaceae, Rhamnaceae, Rutaceae, Santalaceae, Sapindaceae, Saxifragaceae, Selaginaceae, Sterculiaceae, Verbenaceae, Zingiberaceae, and Zygophyllaceae.

Family Nymphalidae (brush-footed butterflies; **Figures 1 and 2**): a group of 4800–6000 species in 14 subfamilies embracing a prodigious variety of forms and sizes, with both sexes having four walking legs; the forelegs are greatly reduced (hence “brush-footed”); adults may be dull brown (Satyrinae and Nymphalinae), brightly colored (Nymphalinae and Brassolini), brilliantly iridescent due to physical properties of the wing scales (Morphinae and Apaturinae), or transparent (Ithomiinae and Satyrinae); some groups are entirely palatable, others highly distasteful, and some (Danainae, Ithomiinae, Heliconiinae, and Acraeinae) are extremely important mimetic models; some species (Charaxinae and Nymphalinae) mainly inhabit tropical forest canopies; adults may feed on flower nectar, pollen, rotting fruits, carrion, or do not feed at all; the caterpillars may bear many spines on the body, some

also have head spines, whereas others are devoid of spines (Figure 2); caterpillars are entirely herbivorous, and the particular groups exhibit strong associations with particular plant families; the pupae are typically suspended.

Subfamily Charaxinae: a group of 350–400 mainly tropical species; adults fly very fast with robust bodies; underside of wings typically camouflaged and leaf-like, some with brilliantly colored upperside (*Agrias*, *Prepona*, and *Charaxes*); all are palatable, with few Batesian mimics (*Consul* and *Euxanthe*); adults feed primarily on juices of rotting fruit, dung, and/or carrion (rarely flower nectar), and most inhabit the forest canopy; caterpillars have smooth bodies, often bearing a corona of head spines or projections; host plant families include Annonaceae, Celastraceae, Convolvulaceae, Euphorbiaceae, Fabaceae, Flacourtiaceae, Lauraceae, Myrtaceae, Piperaceae, Poaceae, Rhamnaceae, Rutaceae, Santalaceae, and Sapindaceae.

Subfamily Apaturinae: a small group of medium to large species that are mainly tropical (often placed within the Nymphalinae); males often with brilliant iridescence on wing upperside, the Neotropical species (*Doxocopa*) with proboscis and forelegs lime-green; adults are strong fliers and feed entirely on carrion and putrefying fruits; caterpillars are herbivores on Ulmaceae and have a smooth body, bifid tail, and head with a pair of strong horns.

Subfamily Satyrinae (satyrs, wood nymphs, and browns): a cosmopolitan group of 1500–2000 mainly tropical species that are generally dull brown (some notable exceptions) with well-developed eyespots on the wings; most feed on juices of rotting fruits, some on fungi, and some on flower nectar in temperate regions; all are palatable, with only few clear examples of Batesian mimicry from Asia (*Penthema*, *Zethenia*, and *Elymnias*); caterpillars are smooth with bifid tails, and some bear paired head projections; host plant families include Arecaceae, Araceae, Cyperaceae, Heliconiaceae, Poaceae, and Selaginellaceae.

Subfamily Brassoliniinae (owls): 70–80 entirely Neotropical species ranging from medium to some of the largest butterflies known (*Caligo*) that fly at dawn and dusk, most with characteristic, large eyespots on the hindwing underside, and they are common in butterfly conservatories; most species feed entirely on rotting fruit juices, but a few with a strongly reduced proboscis (*Brassolis* and *Dynastor*) may not feed; caterpillars have smooth bodies, often with dorsal pseudospines, bifid tails, and multiple horn-like projections on the head; host plant families include Arecaceae, Bromeliaceae, Heliconiaceae, Musaceae, and Poaceae, and they can be pests in banana and palm plantations.

Subfamily Amathusiinae (fauns and duffers): an Indo-Australian group of approximately 80 species (sometimes placed in Brassoliniinae or Morphinae); medium to large butterflies that fly at dawn and dusk and feed on rotting fruit juices; the group is palatable (except for perhaps *Taenaris*) and shows little or no mimicry; caterpillars have smooth bodies, some with long, downy setae, bifid tails, often with paired head horns; host plant families include Arecaceae, Musaceae, Poaceae, and Smilacaceae.

Subfamily Morphinae (morphos; Figure 2): a group of 40–50 Neotropical species of medium to very large butterflies; the large reflective blue species (*Morpho*) are immediately noticeable in nature and in butterfly conservatories, but others

that fly in the forest understory (*Antirrhoea* and *Caerois*) are seldom observed; all feed on rotting fruits, none are considered to be unpalatable, and none are mimics; a favorite of collectors and butterfly conservatories, surprisingly little is known of their natural history; caterpillars are covered with red, yellow, and green patterns, bear tufts of dorsal and lateral setae, possess bifid tails, and bear short, paired projections on the head (Figure 2); host plant families include Arecaceae, Bignoniaceae, Fabaceae, Menispermaceae, Poaceae, and Sapindaceae.

Subfamily Calinaginae: a group represented by two to five species in the genus *Calinaga* restricted to the Himalayan regions; it is apparent that *Calinaga* forms mimicry complexes with *Parantica* (Danainae), but it is not clear if it is Batesian or Müllerian mimicry; caterpillars are smooth with short bifid tails and stout head horns and feed on Moraceae.

Subfamily Nymphalinae: a diverse, cosmopolitan group of more than 3000 species (sometimes split into Limenitinae and Nymphalinae) containing a tremendous range of size and color patterns; some are migratory (*Vanessa*, *Eunica*, and *Salvia*), some are unpalatable models, some are palatable mimics, some show tremendous seasonal polymorphism (*Junonia*), some feed on flower nectar, others feed on rotting fruits and carrion; some groups inhabit tropical forest canopies (*Euphaedra*, *Cymothoe*, *Panacea*, *Epiphile*, and *Baeotus*), some pass north temperate zone winters as adults (*Nymphahlis*); caterpillars usually covered in spines, many with well-developed pairs of head spines (Figure 2); pupa often with bifid projections on head; host plant families include Acanthaceae, Caprifoliaceae, Convolvulaceae, Euphorbiaceae, Fagaceae, Flacourtiaceae, Lamiaceae, Loranthaceae, Moraceae, Plantaginaceae, Poaceae, Rubiaceae, Rutaceae, Salicaceae, Sapindaceae, Scrophulariaceae, Urticaceae, and Verbenaceae.

Subfamily Acraeinae: a group of approximately 250 tropical African species, with a few in Asia and the neo-tropics; ranging from small to large, all are slow-flying unpalatable species that contain cyanogenic compounds, forming aposematic models for a variety of other groups, and are involved in Müllerian mimicry (*Acraea*, *Bematistes*, and *Actinote*); one species (*Acraea encedon*) is almost entirely female and reproduces via parthenogenesis; caterpillars (many which feed gregariously in communal nests) are densely covered in spines, but lack head spines; host plant families include Asteraceae, Passifloraceae, Sterculiaceae, Tiliaceae, and Urticaceae.

Subfamily Heliconiinae (passionflower butterflies): a group of 70–80 mainly Neotropical species with a few in Asia; most with well-developed eyes that are wider than the thorax, elongate forewings, and most serve as models in Batesian and Müllerian mimicry complexes; they feed on flower nectar, and some on pollen (*Heliconius* and *Laparus*) from which they can derive some of their unpalatability; caterpillars are densely spiny, bear paired head spines, and feed entirely upon plants in the Passifloraceae and allies—hence the name passionflower butterflies.

Subfamily Danainae (milkweed butterflies, tigers, and crows): a cosmopolitan group of approximately 150 species, with most in tropical Africa and Asia; ranging from medium to large size, most are slow flying, conspicuously colored, and models in mimicry complexes (*Danaus*, *Amauris*, *Idea*,

Tirumala, and *Parantica*); their distasteful nature derives from feeding as caterpillars on milkweeds, but they also acquire other chemical defenses by feeding as adults on flowers and wounds in certain plants containing particular alkaloids; males often have well-developed, brush-like scent hairs they use during courtship; caterpillars are smooth, often patterned with alternating bands of black, white, and yellow, and many have dorsal pairs of fleshy tubercles; the pupae are frequently reflective gold or silver; host plant families include Apocynaceae, Asclepidaceae, and Moraceae.

Subfamily Ithomiinae (ithomiines and glass wings; **Figure 1**): approximately 300 entirely Neotropical species; adults typically with a very small head, elongate wings, and species vary in color from transparent (*Greta*, *Ithomia*, and *Pteronymia*) to bright tiger-striped patterns (*Mechanitis*, *Tithorea*, and *Melinaea* (see **Figure 1**)); they are involved in both Müllerian and Batesian mimicry, representing unpalatable models for many other groups; their unpalatable properties derive from larval host plants and chemicals acquired by adult feeding, and males typically possess a tuft of scent hairs between the wings that disseminate pheromones; caterpillars are smooth, often with fleshy tubercles, and may be brightly colored or cryptic; The pupa is often reflective gold or silver and squat; host plant families include Apocynaceae, Gesneriaceae, and Solanaceae.

Subfamily Tellervinae: a group of 6–10 Australasian species all in the genus *Tellervo*; they serve as models for nymphaline and satyrine Batesian mimics; this group has been included within the Ithomiinae; the caterpillars resemble some Danainae and feed on Apocynaceae.

Subfamily Libytheinae (beaks and snout butterflies): a cosmopolitan group of approximately 10 species recognized by the large erect palpi that form a “snout”; most species are well-known to periodically undergo spectacular migrations; the caterpillars somewhat resemble those of the Pieridae, and all feed on Ulmaceae.

Early Stages and Host Relationships

Like all members of Lepidoptera, butterflies have four discrete stages in the life cycle (egg, caterpillar, pupa, and the adult), each with particular characteristics, behaviors, and requirements. Furthermore, to complete their life cycle, butterflies require a plant or insect host to feed on.

Egg

Butterfly eggs are laid either singly or in small to large clusters, either on or off the host, and the location where the egg is laid is typically important (**Figure 2**). The eggshell frequently has an elaborate sculpturing that plays a role in respiration, and each major group of butterfly has its own form of egg.

Caterpillars

Depending on the group, the appearance of butterfly caterpillars may range from cryptic to aposematic, they may be covered with spines and/or hairs or appear to be naked, and

their diets may include plant tissue or the flesh of other insects or they may feed entirely on secretions produced by other insects (**Figure 2**). All caterpillars consist of three major sections: the head, thorax, and abdomen. The hardened head houses mandibles that function to shear off bites from their food. The head bears a gland that lays down silk that is grasped as the caterpillar moves forward, helping the caterpillar grip the substrate and also to secure rolled leaves in which they may shelter. Each thoracic segment bears a pair of true legs, whereas the 10 abdominal segments form the bulk of the body, housing the long gut. Caterpillars walk by using the prolegs (segments 3–6 and segment 10), and these function by hydraulic pressure and muscles. Segments 1–8 bear the external ring-like orifices (spiracles) that allow gas exchange with the atmosphere.

After reaching a particular size each caterpillar instar stops eating and undergoes a molt to the next instar; this is how caterpillars grow. Generally, but not always, there are five larval instars followed by a molt to the pupa, or chrysalis. Caterpillar growth is not a steady increase in weight from first to final instar; rather, there is a dramatic fluctuation of weight between each molt. Newly molted caterpillars may weigh about the same as or even less than previous instars, but their weight will quickly increase and exceed that of previous instars.

Caterpillar feeding behavior often differs among instars. In many groups, late-instar caterpillars may stop feeding during the day and then feed entirely at night. Alternatively, some lycaenid caterpillars may start life feeding on plants and, after molting to a later instar, they fall off the plant, are picked up by ants, and are carried into their nest where the caterpillars feed as carnivores on ant brood.

Pupa

When the final-instar caterpillar is fully grown, it stops eating and enters its molt to the pupa, or chrysalis. Within the pupa the caterpillar tissues are reconstructed into the adult by the process known as metamorphosis. The pupa attaches to a substrate by a series of hooks on the last segment (cremaster), and major groups typically have characteristic manners of pupation. For example, pupating with the head downward attached only by the cremaster is typical of Nymphalidae, but pupae of Papilionidae and some Pieridae attach by the cremaster with head upward and are restrained by a silk girdle. Pupae of Lycaenidae produce a whirring, clicking, or buzzing sound with a rasp and file system on the abdomen that may be a defense against predators. Sound production is also known in some nymphalid pupae. When mature, the pupa splits along its dorsal surface, and the adult ecloses. After eclosion, the adult normally hangs from the pupal shell or nearby with the wings suspended downward so that it can expand and dry its wings. If dried in a crumpled manner the wings are useless for flying, and the butterfly is effectively dead. As a rule, female butterflies are mated soon after or even before eclosion, exemplifying one of the most potent laws of evolution—nature abhors a virgin.

Adult

The adult butterfly (**Figure 1**) is incapable of additional growth but is capable of flight, mating, and reproduction. Like

all insects, the butterfly body is composed of the head, thorax, and abdomen.

The most obvious features of the butterfly head are the large compound eyes composed of numerous facets (ommatidia) that cannot focus but are sensitive to movement, light, and certain colors. A pair of distally thickened antennae arise from between the eyes that vary in shape according to the group. The antennae function as sensory organs for finding food, mating, and balance during flight and are sensitive to volatile chemicals. Between the eyes there is a pair of appendages called labial palpi, and between them lie the proboscis, a hollow tube composed of two interlocking halves that is coiled like a watch spring when not in use and can be extended for feeding. By virtue of having a proboscis, butterflies are restricted to a liquid diet that may include flower nectar, the juices of rotting fruit, carrion, dung, or semi-digested pollen. Proboscis length may vary according to the group; in some species it is nearly vestigial, thus precluding feeding as adults (*Brassolis* and *Liphyra*), whereas in others the proboscis measures more than 1.5 times the length of the body (*Eurybia*), allowing them to take nectar from a wide range of flowers.

The thorax is composed of three fused segments bearing the wings and legs, and it contains the muscles for locomotion and various internal organs. As in all insects, the adult butterfly has six legs, one pair per segment. Butterflies have four wings (two forewings and two hindwings) typically covered in scales that give butterflies their characteristic colors and patterns. The color patterns of butterflies result mainly from the covering of scales that are arranged like overlapping roof tiles. There are three notable types of scales. The pigmentary scales are colored by the deposition of melanin, pterins, or other chemicals. Structural scales generate blue, violet, copper, or green colors by reflecting particular wave lengths of incident light. Androconial scales store and disseminate chemical odors (pheromones) that are used in mating, and some of these scales may be physically transferred to the female during mating.

The abdomen houses the digestive and reproductive tracts, terminating in the reproductive organs (genitalia). Except for segments housing the genitalia, the abdomen can stretch when the gut becomes filled with food, and abdominal distention may be considerable in groups feeding on rotting fruits (*Charaxinae*). The penultimate abdominal segment of males bears two appendages (claspers) that open to expose the aedeagus (penis) and serve to grip the female's abdomen during mating. The female abdomen terminates in three openings: the anus, egg pore, and copulatory pore. The configuration of genitalia is used extensively in butterfly taxonomy.

Host Relationships

An important aspect in the butterfly life cycle is the ability of ovipositing females to find, and caterpillars to feed on, particular plants. The liaison with plants is so strong that many groups of butterflies only associate with particular taxonomic groups of plants; other plants are unacceptable to both caterpillars and ovipositing females. In the *Lycaenidae* this

association may extend to particular species of ants or Homoptera. For example, caterpillars of milkweed butterflies (*Danainae*) only feed on plant families containing milky latex, and those of the *Heliconiinae* use plants in the *Passifloraceae*. Such patterns of host association in butterflies gave rise to Ehrlich and Raven's classic paper that developed the concept of coevolution. On the whole, host association records for the *Papilionidae*, *Pieridae*, and *Nymphalidae* are much more complete than for the *Lycaenidae*.

Butterfly–Ant Symbioses

The ability to form symbiotic associations with ants (myrmecophily) occurs only within the *Lycaenidae*. Here, caterpillars provide food secretions to ants in exchange for protection against insect predators such as social and parasitic wasps. To form these symbioses, caterpillars have a suite of unique adaptations that may include organs (collectively known as ant-organs) to produce food secretions, volatile chemicals, and sound, all of which work in concert to modify ant behavior and enhance the protective attitude of ants toward caterpillars. Recent studies on ant-organs indicate that myrmecophily evolved at least twice in the butterflies: once in the *Riodininae* and independently in other lycaenid subfamilies.

The widespread trait of myrmecophily within the *Lycaenidae* and the fact that lycaenids account for approximately 50% of all butterfly species led Pierce (1984) to suggest that myrmecophily has amplified speciation rates in this group. Indeed, the diversity of life histories in myrmecophilous butterflies can be exceedingly complex, encompassing herbivores, carnivores, and those that feed as caterpillars only on secretions, and the associations with ants range from mutualistic to completely parasitic or predatory.

Food Secretions

Ants pay close attention to particular abdominal segments bearing ant-organs that produce food secretions, which in some species are known to have high concentrations of amino acids and sugars. In some *Riodininae*, these consist of a pair of organs (tentacle nectary organs) on the eighth abdominal segment that can be extruded individually or simultaneously. In all other lycaenid subfamilies, this organ is a single dorsal pore on segment 7 (dorsal nectary organ). Ants are so intent on obtaining the secretions that they constantly antennate the caterpillar to solicit more, and in many cases, this is a good example of a general rule among participants in symbiotic associations—“you scratch my back and I'll scratch yours.”

Semiochemical Production

Myrmecophilous caterpillars may have extrusible glands that seem to produce volatile chemicals (semiochemicals or pheromones) that alter the behaviors of attending ants. Some *Riodininae* have a pair of extrusible glands on the third thoracic (anterior tentacle organs), whereas other lycaenids have a pair of glands on the eighth abdominal segment (tentacle organs). In both cases, when extruded from the body these organs do not

produce a liquid secretion but rather the tip is modified with spines that gives the appearance of a tiny feather duster. These spines likely provide a larger surface area to disseminate volatile chemicals that may be similar to ant alarm pheromones. Instead of anterior tentacle organs, a small group of Riodininae caterpillars (*Theope*) possess a corona of inflated setae around the head that appear to disseminate semiochemicals.

Call Production

The idea that caterpillars produce acoustic calls might seem unlikely. We now know, however, that myrmecophilous caterpillars produce substrate-borne calls that function in the formation and enhancement of their symbioses with ants, and these calls bear similarities to those produced by ants for communicating among themselves. In most Riodininae caterpillars calls are produced by a pair of mobile, grooved, rod-like appendages (vibratory papillae) arising from the distal edge of the first thoracic segment. An acoustical signal is produced when the grooves on the vibratory papillae grate against head granulations (Figure 2). In other lycaenid caterpillars the call is produced by thickened bumps located ventrally between abdominal segments. Most concepts of insect communication suggest that acoustical calls evolved in a sexual context. However, caterpillar calls provide an example showing that, by forming symbiotic associations, the call of one species may evolve to attract another, unrelated species.

Ants and Caterpillar Associations

In general, myrmecophily in caterpillars occurs with a particular type of ant. A basic element among myrmecophilous caterpillars is that they typically form symbioses only with ant species that depend heavily on secretions as food—ants that also form symbioses with Homoptera and plants. Therefore, secretion-harvesting ants likely played a key role in the evolution of myrmecophily, whereas those ants that are predators or herbivores did not. An ecological consequence of the evolution with secretion-harvesting ants is that in any suitable contemporary habitat, a suite of caterpillar, plant, and Homoptera species all share the same species of ant symbionts.

Among myrmecophilous caterpillars there are two main categories of ant association. The most widespread category comprises an association in which a particular caterpillar species may be tended by a suite of secretion-harvesting ant species. The other category comprises an association in which a caterpillar has an obligate association with a single species of ant. In this case, female butterflies may require the presence of a particular ant species to lay their eggs since caterpillars are unable to form symbioses with any other ant species. Furthermore, it is in these types of associations in which some caterpillars are adopted by the ants, taken into the nest, and become parasites or predators of their hosts.

Butterfly Mimicry and Diversity

When several species of butterflies share conspicuously bright color patterns and fly together in the same habitat, this is

called mimicry—a widespread and important antipredator defense. Fundamentally, mimicry occurs when one species closely resembles another species, and based on outward appearance one or both are avoided by predators. Virtually all major taxonomic groups of butterflies exhibit mimicry, but the warningly colored (aposematic) models are found predominantly in particular groups of Papilionidae, Pieridae, and Nymphalidae, whose caterpillars feed on poisonous plants. Mimicry is a complex and subtle topic, but there are two basic types of mimicry in butterflies, both involving species that advertise conspicuous color pattern to predators: Batesian and Müllerian mimicry.

Batesian Mimicry

This is the phenomenon whereby one or more palatable species resemble one or more unpalatable model species, and the palatable species gain protection by duping predators. Here, predators avoid mimics because they resemble unpalatable models. The best known basic example of Batesian mimicry involves the palatable viceroy (*Limnitis archippus*) and the unpalatable monarch butterfly (*Danaus plexippus*) in North America. However, Batesian mimicry occurs in all biogeographic regions, and one of the most intriguing examples involves the sex-limited mimicry of the wide-ranging African swallowtail, *Papilio dardanus*. Here, only the females are mimics. In this case, females are polymorphic with respect to their appearance, and their color patterns change geographically when flying with different model species. In other words, *P. dardanus* females from Kenya may look entirely different from those from Zaire or elsewhere, and in each instance they precisely mimic a different unpalatable model species. Thus, the type of female color pattern evolves in response to and depends on the local community diversity of the model species.

Müllerian Mimicry

This is the phenomenon whereby several unpalatable species (co-mimics) fly in the same area and share the same color pattern. In this case, the association of similarly patterned unpalatable species is thought to reinforce the nasty experience predators have when eating butterflies of such a color pattern, thus educating predators to avoid it.

Mimicry and Diversity

Aposematic species are an important element of butterfly diversity, particularly in the tropics. For example, approximately 20–25% of all Papilionidae, Pieridae, and Nymphalidae in Costa Rica and Kenya are clearly aposematic models. Although accounting for a large percentage of all butterfly species, there are few documented examples of aposematic Lycaenidae.

Müllerian mimicry is primarily a tropical phenomenon and is an important part of tropical faunal diversity. This can be appreciated by considering the diversity of color patterns shown by many co-mimetic species and races of ithomiine and heliconiine butterflies (plus many co-mimic moths and other butterfly groups) that converge across large areas of the

neotropics. Even when the tightly overlapping distribution of only two co-mimetic species of *Heliconius* and their many precisely convergent color patterns are mapped over the Neotropical region, one cannot doubt the power mimicry plays in the evolution, organization, and diversification of tropical butterfly faunas. The numerous co-mimetic species of Acraeinae butterflies throughout the African region also serve as another potent example of the influence of mimicry on the diversity of butterfly communities. It is clear that butterfly mimicry evolved in the context of multispecies interactions which involved butterflies, their predators, and the plant and insect hosts they feed on as adults and caterpillars. Thus, mimicry serves to remind us that habitat disturbance and/or destruction may have important implications for the continued survival and future evolution of interacting species.

Geographical Patterns of Butterfly Diversity

One of the most frequently asked questions about butterflies is the following: How many are there? The answer is thought to be between 12,900 and 15,819 species. This is hardly a satisfying answer since the question has little biological context. In contrast, questions framed by comparing different geographical areas impart a sense of dynamics to butterfly diversity. For example, one might ask: Does butterfly species diversity change with respect to latitude? or How do different areas of Africa compare with respect to numbers of butterfly species? Indeed, comparing species numbers among areas shows that latitude, biogeographical region, area size, and taxonomic affinity all contribute to global butterfly species diversity. A caveat is in order about comparative species numbers: Sampling effort is almost always unequal among different areas, and the taxonomic accuracy of species counts or lists often varies among sites. Thus, it is prudent to use care when interpreting the generality of species diversity patterns among areas.

Table 1 Approximate numbers of American and world butterfly species

	North America	Neotropics	World
Papilionidae	35	169	621–645
Pieridae	63	347	1086–1105
Lycaenidae	171	2300–3000	6000–6900
Nymphalidae	202	1850–2500	5175–5975

Latitudinal Gradients of Species Diversity

As is the case for most groups of terrestrial organisms, butterfly species diversity increases toward the equator. Comparing the North American and Neotropical faunas suggests that the neotropics has an estimated 10–12 times more butterfly species compared to North America (Table 1). Comparing site diversity at different latitudes, however, provides a richer perspective of this phenomenon. A latitudinal transect using five well-known sites from the Americas makes it obvious that species numbers increase when moving from the north latitudes toward the equator (Table 2), even though the smallest areas being compared are at the equator. The dramatic equatorial increase in species is exemplified by the fact that a mere 500 ha of lowland Ecuadorian forest has more butterfly species than all of North America.

The relative contribution of each butterfly family to site diversity also varies with latitude. From Table 2, it is evident that the relative contribution of Papilionidae and Pieridae to total species diversity is about the same regardless of latitude, but the contributions of Nymphalidae and Lycaenidae increase dramatically between 20 and 0° latitude (Figure 3). The increase in species of Nymphalidae is accounted for by subfamilies that reach their greatest diversity in the Amazon (Morphinae, Brassolinae, Charaxinae, Satyrinae, and Ithomiinae), whereas the increased contribution of Lycaenidae is due mainly to the subfamily Riodininae, which is also an Amazonian group.

Variation Among Neotropical Sites

Species diversity is not equal among Neotropical forest sites. Nine well-known sites that have many species in common vary strongly in numbers of species and in the contribution of each family to species diversity (Table 3). Here, species numbers may range from 212 in Mexico to 1199 at one Brazilian site. Among six Amazonian sites, numbers range from 676 to 1199 species. When averaged over the entire Table 3, the contribution of each family to species diversity is as follows: Papilionidae, 3.8%; Pieridae, 4.8%; Nymphalidae, 45.2%; and Lycaenidae, 46.1%. It may be significant that these proportions approximately reflect those observed when comparing latitude (Figure 3).

Comparisons among sites from the Americas point to the general relationship of the higher species richness that occurs at lower latitudes and to the marked variation among sites that share many species in common. These examples also show that the relative contribution of each family to species richness

Table 2 Latitudinal transect showing changes in American butterfly species diversity

Site	Latitude	Area	Family				Total species
			Papilionidae	Pieridae	Nymphalidae	Lycaenidae	
H. J. Andrews Forest, Oregon	44°14'	6400 ha	5	7	27	23	62
Los Angeles Basin, California	34°4'	> 1 million ha	6	15	26	32	79
Estacion Los Tuxlas, Mexico	18°35'	700 ha	14	19	113	66	212
La Selva, Costa Rica	10°26'	1000 ha	16	26	219	181	442
Garza Cocha, Ecuador	0°29'	500 ha	24	25	314	312	676

is not equal; the proportion of nymphalid and lycaenid species increases toward the equator, but the proportion of papilionid and pierid species appears relatively constant. At this point, we might ask if there are similar patterns outside the neotropics.

Regional Patterns of Species Diversity

Although most butterfly species are tropical, the number of species is not distributed equally among tropical regions (Table 4). As one might expect, those areas closest to the equator have a greater number of species, but there is also an effect of size on species diversity (Table 4). In this comparison, the continent of Africa has by far the most species, but it also encompasses the greatest geographical area and habitat types (deserts, mountains, forests, and savannas) of any area. Within Africa there are more species in Zaire than in Kenya or Southern Africa, highlighting the ecological diversity in African climate and habitat types. Thus, the entire continent

Figure 3 Latitudinal gradient of American butterfly species diversity. Each line represents species numbers per family contributed to five sites distributed from 44° north to the equator.

of Africa should contain more species than a geographic subset.

As in the neotropics, the relative contributions of families to total species numbers differ among areas of Africa (Table 4). Here, the Papilionidae and Nymphalidae contribute equally to total richness of both Kenya and Zaire, but Kenya shows an increased proportion of Pieridae and a decreased proportion of Lycaenidae. On the other hand, the proportional contributions of Papilionidae and Pieridae are reversed in the Zaire fauna. The Papilionidae and Nymphalidae in the Southern African fauna contribute less to the total than other mainland African areas, but nearly 55% of all Southern African butterflies are Lycaenidae. Overall, these proportional differences (Table 4) may reflect the ecological responses of taxonomic groups to differences in habitat types and/or the differences among regional taxonomists. Finally, in comparison to mainland Africa the fauna of Madagascar is interesting. Here, only 17% of all butterflies are lycaenids, but nymphalids constitute 67% of the total fauna, most of which are Satyrinae (i.e., 42% of all the butterflies). This example demonstrates how historical colonization and subsequent radiation of an island by one group can produce a fauna distinctly different in composition from that of the mainland.

Only a broad-brush comparison among areas of different sizes and regions is necessary to appreciate that, overall, butterfly diversity is highest in the neotropics (Tables 1–5). Despite the great disparity in geographical area in the comparison, the small country of Costa Rica has a greater percentage of the world's butterfly species than does North America, Australia, New Guinea, or the peninsula of Malaysia (Table 5). Since our taxonomic understanding of African, Australian, and Oriental butterflies is more thorough than that of the neotropics, it is likely that the total Neotropical butterfly species count will increase in the future.

Species Diversity in Space and Time

When estimating species diversity in any habitat, the variables of time, space, and sample size can be profoundly important. For example, consider two samples taken in the same Wisconsin prairie—one for 7 days in mid-July and the other for 7 days in mid-January. Despite equal sampling effort, the number of species tallied in January would certainly be zero

Table 3 Comparative diversity among neotropical sites^a

Site	Family				Total species	Total area (ha)
	Papilionidae	Pieridae	Nymphalidae	Lycaenidae		
Estacion Los Tuxlas, Mexico	14 (6.6)	19 (8.9)	113 (53.3)	66 (31.1)	212	700
Finca La Selva, Costa Rica	16 (3.6)	26 (5.8)	219 (49.5)	181 (40.9)	442	1,000
Garza Cocha, Ecuador	24 (3.5)	25 (3.7)	315 (46.6)	312 (46.1)	676	500
Jatun Sacha, Ecuador	25 (3.6)	23 (3.2)	306 (43.7)	345 (49.3)	699	600
Paquitza, Manu, Peru	25 (2.9)	31 (3.6)	369 (43.3)	427 (50.1)	852	3,900
Tambopata, Peru	25 (3.1)	26 (3.3)	337 (42.3)	409 (51.3)	797	>2000
Cacaupata, Brazil	30 (2.5)	31 (2.6)	423 (35.3)	715 (59.6)	1199	2,000
Alto Jurua, Brazil	38 (3.7)	37 (3.6)	467 (45.0)	496 (47.8)	1038	>500
Cerro do Japi, Brazil	19 (4.7)	36 (8.9)	193 (47.8)	156 (38.6)	404	>400

^aThe percentage of the total species at a particular site is in parentheses.

Table 4 Variation in the contribution of each family to species richness among different faunas^a

Fauna	Family				Total
	<i>Papilionidae</i>	<i>Pieridae</i>	<i>Nymphalidae</i>	<i>Lycaenidae</i>	
All of Africa	80 (2.9)	145 (5.3)	1107 (40.6)	1397 (51.2)	2729
Zaire	48 (3.7)	100 (7.6)	607 (46.5)	551 (42.2)	1306
Kenya	27 (3.7)	87 (12.1)	335 (46.5)	271 (37.6)	720
Southern Africa	17 (2.3)	54 (7.2)	265 (35.6)	409 (54.9)	745
Madagascar	13 (4.9)	28 (10.7)	175 (66.8)	46 (17.5)	262
Australia	18 (6.5)	35 (12.6)	85 (30.6)	140 (50.3)	278
New Guinea	41 (5.2)	146 (18.6)	222 (28.3)	376 (47.9)	785
Malaysia	44 (5.8)	44 (5.8)	273 (35.9)	400 (52.5)	761
Costa Rica	42 (4.0)	71 (6.8)	438 (41.9)	493 (47.2)	1044

^aThe percentage of total faunal richness by each family is given in parentheses.

Table 5 Percentage of world species by geographical region^a

	Region						
	North America	Neotropics	Costa Rica	Africa	Australia	New Guinea	Maylasia
Total species	471	5341	1044	2729	278	785	761
% World fauna	3.4	38.8	7.6	19.8	2.0	5.7	5.5

^aTotal number of butterfly species for world fauna (13, 753.5) and the neotropical region (5341) represent averages.

because no butterfly is known to fly in a prairie during mid-winter. Here, it is easy to see that time of sampling is important for estimating species diversity.

The problem of sampling in space and time becomes more important in forest areas, especially tropical ones. Consider a recent study of fruit-feeding nymphalid butterflies conducted on 600 ha of lowland Ecuadorian rain forest that investigated how species were distributed in space and time. To ensure equal sampling, butterflies were simultaneously trapped in the canopy and understory for the first week of every month for a period of 1 year. The results showed that both time of sampling (month) and position of trap (canopy or understory) were extremely important in estimating species diversity at this site (Figure 4). In other words, had the study sampled for only a few months, or only in the understory, species diversity would have been greatly underestimated. A similar study from a different site in Ecuador also demonstrated that a significant proportion of species diversity was accounted for by time of sampling and the forest canopy fauna. This study further showed that species diversity varied significantly over short distances within the same, seemingly uniform rain forest, and it highlights the importance of sample size in comparisons of species diversity (Figure 5). Such studies illustrate the critical nature of sampling methods, space, time, and sample sizes in comparisons of butterfly diversity.

Butterfly Diversity and Habitat Destruction

It is obvious that the evolution of butterfly diversity is based on historical and contemporary interactions with many

Figure 4 Monthly variation in species richness (top) and abundance (bottom) of fruit-feeding Nymphalidae in forest canopy and understory (reproduced from DeVries PJ (1997) *The Butterflies of Costa Rica and Their Natural History. II. Riodinidae*. Princeton, NJ: Princeton Univ. Press).

Figure 5 Species diversity of fruit-feeding Nymphalidae showing the relationship to space and sample-size. Each numbered line represents a plot sampled from within a single tract of continuous rainforest (reproduced from DeVries PJ, Walla TR, and Greeney H (1999) Species diversity in spatial and temporal dimensions of fruit-feeding butterflies from two Ecuadorian rainforests. *Biol. J. Linnean Soc.* 68: 333–353).

species. These biological interactions include plant and/or insect hosts, co-mimics in Batesian and Müllerian mimicry complexes, predators, and parasites. Butterflies have also evolved within and adapted to a great many biomes, habitats, and microhabitats, ranging from the multilevels within lush tropical rain forests to starkly dry deserts and subarctic tundra.

Habitat destruction always has profound effects on the biological communities that inhabit them, and butterflies are no exception. Like all organisms, butterflies live, evolve, and diversify within dynamic biological systems, and as such they cannot be studied as art objects or protected as inventoried stock. To date, butterflies have served as tools for understanding the diversification of life on Earth and the fundamental interactions among species. However, our future understanding of butterfly diversity will depend on a renewed interest in studying them in the natural world and valuing the habitats in which they occur.

Acknowledgments

Glossary

Antennules, antennae (pl.) Antennules are the first pair of sensory appendages on the head, and antennae are the second pair of sensory appendages on the head of crustaceans.

Benthic, epibenthic Living at the bottom of the sea; *epi* = upon, thus epibenthic organisms live on top of sediment or hard substratum.

Brackish Less salty than sea water.

Chelate, subchelate, chela (s.), chelae (pl.) Chelate means having a pincher-like claw (usually due to an extension of the second from terminal segment beside the terminal segment, forming the claw). In subchelate forms, the terminal segment merely folds back on the second from terminal segment. The chela is the clawlike appendage.

Commensal, symbiotic Living in association with (e.g., on or in) another organism.

Crepuscular Active in dim light conditions, such as dusk or dawn.

Dorsal, ventral Dorsal part of the organism is the “back,” on the opposite side of the body from the mouth; ventral is the same side of the body as the mouth and legs for a crustacean.

Extant Living.

Furca (s.), furcae (pl.) Forked structure, usually associated with the telson in crustaceans.

Gonochoristic Individual is either a male or a female throughout life.

Hypersaline More salty than seawater.

Interstitial Living among sand or silt grains; usually refers to an aquatic benthic environment, the intertidal, or in groundwater.

Invertebrates Animals (usually used in reference to phyla or major taxa) that lack backbones.

Macrobiota Organisms large enough to see, usually greater than 1 mm.

Median, medial Along or toward the midline of the body.

Phyllopod A leaflike appendage.

Pleopod Abdominal appendage in crustaceans.

Polyphyletic A group of species or lineages that have independent origins instead of being descended from a common ancestral group.

Protogynous, protandrous Different types of hermaphroditism (in contrast to gonochoristic). Individuals in protogynous species develop into a reproductive female early in life, then change sex and become a reproductive male later in life. Individuals in protandrous species are functional males first, then females.

Rami (pl.) A cuticular extension (usually relatively long and thin, can be leaflike) from the body (e.g., caudal rami = extension from the posterior segment of the body, usually paired in crustaceans).

Setae (pl.) Bristle- or hairlike extensions of the cuticle that are characteristic of arthropods and related phyla.

Taxon (s.), taxa (pl.) A group of organisms with shared similarities at any level of a taxonomic scheme (could be a species, genus, family, order, etc.).

Telson Most posterior segment of the body in crustaceans, usually flattened and often armored.

Thoracopod Appendage on the thorax (paired in crustaceans).

Uniramous, biramous, triramous, polyramous An extension of the body (usually an appendage) having one, two, three, or many branches (e.g., triramous antennae have three main branches or flagellae).

Vestigial An organ or structure that is present only in rudimentary form (probably lost from a previous condition).

Summary and Definition of Biodiversity in Crustacea

In the last two decades of the twentieth century, it became evident to both the scientific and much of the lay public that the health of the earth's living biota—the foundation of human existence—is seriously threatened by environmental changes, mostly generated by the exponentially increasing activities of humans. This realization was made more poignant by the simultaneous recognition that our knowledge of the diversity of the world's animals, plants, fungi, and microorganisms is woefully inadequate even to assess the amount of diversity present and the degree of risk faced by different components of the global biota (Wilson, 1985, 1992).

The term “Biological diversity” and its shortened form “biodiversity” were introduced by Norse and McManus, (1980), Lovejoy (1980), and the National Forum on Bio-Diversity, held at the Smithsonian Institution (1986). Whereas “biological diversity” was first defined to include the concepts of genetic diversity (variability within species) and ecological diversity (number of species in a community of organisms; Norse and McManus, (1980), the term “biodiversity” was formalized and popularized in the Proceedings of the National Forum (Wilson and Peters, 1988) to include an appreciation for the range of all of the different levels and types of biotic diversity found on earth, including the processes that generate and maintain diversity, and is thus followed here. “Diversity” sometimes implies concepts about the degree of

evenness in abundance among species as well as number of species, but, for simplicity and convenience, the terms "diversity" and "biodiversity" will be used interchangeably here to indicate the number of species or higher taxa in a group and to encompass the range of structural variation, habitat characteristics, ecological roles, life history traits, and biogeographical characteristics of particular groups of organisms. The diversity of these features, including the uniqueness of certain adaptations or lineages, often can be comprehended best in the context of the ecological and evolutionary processes that generate these patterns of variation.

To properly evaluate biodiversity in Crustacea, we need to know the range of major ways of life of different groups of crustaceans, as indicated in their body plans. These architectural differences are reflected in the number of higher taxonomic groups within taxa and provide insights into the diversity of ecological processes in which the group participates.

Ecological diversity includes the range of habitats that the group occupies, whether the group lives in unique environments or species assemblages, and the diversity and importance of the ecological roles that taxa within the group play in their natural communities. For example, are the species low on the food chain (thus supporting the diversity of the rest of the community), do they affect community structure as top predators, do they determine diversity of the community by engineering the physical environment? Other important components of biodiversity include the phylogenetic history and uniqueness of lineages. Some groups of Crustacea represent the only surviving remnants of lineages that have persisted for half a billion years. Because of their early derivations, such groups are likely to be unique in their genetic, morphological, physiological, or ecological adaptations. Such a historical legacy merits special conservation attention. Similarly, the diversity of life history patterns is intimately related to genetic variability within and among populations. Some crustaceans show rapid maturation, short life spans, and massive reproductive effort, while others live for extended periods (often many years) and are morphologically and behaviorally adapted for strong interactions with other species. Some produce a few large offspring that develop directly into juvenile stages similar to the adults and do not disperse far from the parental population. Other species release huge numbers of tiny offspring, entirely different in form from the adults, that feed for extensive periods in the plankton and disperse great distances. Many of these patterns track within lineages and are correlated with body size. High variability among individuals within populations, frequently associated with wide dispersal of pelagic offspring and wide geographic ranges of species, may enable a population to persist in spite of environmental changes. However, high variability among populations (often associated with lower gene flow and isolated endemic populations) may increase the probability of losing entire genetic complements if local populations are eliminated by environmental change. Distributional patterns, particularly at the species level, are one of the most important and neglected aspects of biodiversity in most groups of organisms, including the Crustacea. The extent of the geographic range of a group, and of species within the group, are some of the most important predictors of extinction in the fossil record

(Jablonski, 1991). Organisms that inhabit highly specialized habitats (especially when these habitats are geographically restricted), occupy high trophic levels, or are of large body size are likely to be vulnerable to extinction because of relatively low total population sizes and their dependence on a reliable food supply or special micro-habitat (both of which fluctuate in many environments). Understanding the paleontological history of crustaceans is essential for understanding the present configuration and future prospects for crustacean biodiversity. The fossil record indicates that recoveries from major mass extinctions require about 10 million years, rendering the process of diversification irrelevant for the survival of humans and other biota over the next 500 years. However, understanding vulnerability to extinction in the past and in the present rapidly changing environment is crucial for assessing present crustacean biodiversity and sustaining it for future generations.

The Setting

Biodiversity in Major Global Habitats, with Special Reference to Marine Environments

Marine environments, the habitat in which crustaceans originated and which continues to sustain the greatest proportion of crustacean species, contain more higher-level biodiversity (different types of organisms represented, for example, as phyla, classes, orders, families, and genera) than other habitats because life arose in the sea, and many of these ancient lineages are still with us. Of plants, animals, and fungi large enough to see, 43 phyla live in the ocean and 28 live on land. Within the 33 animal phyla, 64% inhabit only the sea while only 5% are exclusively land dwellers, and 90% of all known classes are marine (May, 1994; Ray, 1991). It is important for humans to know and understand the diversity of these marine lineages, with all of their bizarre body plans and adaptations, in order to understand how life evolved and how we fit into it. Of more immediate urgency, marine organisms provide a critical source of protein for humans. This fact will become more important in the 21st century and beyond (especially in the world's tropical countries, which are experiencing rapid population growth and associated environmental degradation). Possibly even more significant in the long run, these marine groups provide a repository of genetic and chemical material that has been evolving, each in its own direction, for more than half a billion years. This genetic and chemical material is much more likely to be novel than the more recent, better-known lineages that invaded land.

Despite its huge expanse and the greater number of higher level groups it supports, the ocean contains fewer known species than the land. Only about 274,000 or 14% of the world's 1.9 million described species are known from the ocean (Reaka-Kudla, 1997). Of these, approximately 200,000 are macrobiota (vertebrates, invertebrates, and plants large enough to see) and 180,000 are macroinvertebrates (groups of marine invertebrates sufficiently big to see). Global freshwater environments contain approximately 44,000 total species (2.4% of all those described), 35,000 species of macrobiota and 26,000 species of macroinvertebrates. There are about

950,000 insects, 80,000 noninsect and noncrustacean (mostly chelicerate) arthropods, and 57,000 other terrestrial macroinvertebrates. Globally, about 100,000 species live symbiotically on or in other organisms (5.3% of all described species); roughly 73,000 of these probably are macrobiota (mostly invertebrates). If we exclude the noncrustacean terrestrial arthropods (chelicerates, insects, and their relatives) because of their unique specializations for life on land, there are approximately 336,000 described macroinvertebrate species in the marine, freshwater, terrestrial, and symbiotic environments. Of these, marine macroinvertebrates constitute 53.6%, freshwater macroinvertebrates 7.7%, terrestrial macroinvertebrates 17.0%, and symbiotic macroinvertebrates 21.7% of the total species. We can use these figures to estimate the numbers of crustacean species that occupy different types of habitats.

There are about 43,000 species of described crustaceans—2.3% of the 1.9 million described species and 12.8% of all macroinvertebrates. If crustaceans inhabit major types of environments in about the same proportions as other nonchelicerate and noninsect macroinvertebrate groups, probably about 23,000 described species of crustaceans live in marine and brackish coastal waters (figures rounded to nearest thousand); this represents about 12% of all species of marine macrobiota. Similarly, if crustaceans have invaded fresh water to about the same degree as other nonchelicerate and noninsect invertebrates, at least 3400 crustacean species likely inhabit fresh waters (rounded to nearest hundred); this represents about 10% of all described freshwater macrobiota. If crustaceans are about equally adapted to land as are other nonchelicerate and noninsect invertebrates, about 7300 crustaceans are terrestrial. This is less than 1% of the global terrestrial macrobiota. Since about 22% of all macroinvertebrate species are symbiotic, probably about 9,500 crustacean species are estimated to be symbionts (about 13% of global symbiotic macroinvertebrates). In fact, parasitism is rampant in some groups of crustaceans. Certainly these figures are underestimates—most likely great underestimates—of the true numbers of species in aquatic and particularly marine environments because these environments are so poorly known. If only 10 to 20% of all crustacean species have been described (discussed later), then there likely are about 200,000 to 450,000 total (known and unknown) species of crustaceans on earth.

The following observations suggest that the numbers of crustacean species, as well as those of other marine phyla, usually are underrepresented. Based on samples of 1597 species of soft-bottom marine macrofauna off the east coast of North America (255 to 3494 m), *Grassle and Maciolek (1992)* calculated that the global deep-sea fauna, primarily because of the huge area it occupies, may include as many as 10 million species (mostly polychaete annelids, crustaceans, and mollusks). Most of these species are small and rare (90% of the species sampled comprised less than 1% of the individuals; 28% of the species in the entire fauna were collected only once). *Reaka-Kudla (1997)* calculated that global coral reefs contain between 1 and 5 million total species (though only about 100,000 described species).

Experts have estimated that about 21% of global crustacean species have been described and that about 26% of global molluscan species are known (*Systematics Agenda 2000,*

1994). These phyla represent the two most commercially important and thoroughly documented invertebrate groups. Only 10% of the relatively well-known isopod crustaceans collected from shallow sediments in southern Australia had been described (*Poore and Wilson, 1993*). Because of the great variation in the extent to which different regions of the oceans have been sampled, these scientists estimated that only 5% of marine invertebrates are known from the oceans overall. Calculations suggest that about 10% of the species on global coral reefs have been described. Scientific descriptions exist for about 17% of the species of algae. The microbiota is even more poorly known. Only 1%, 1 to 10%, 4 to 7%, and 2 to 3% of the total species of the viruses, bacteria, fungi, and nematodes have been described.

Although the ancient major groups (phyla, classes) of marine organisms are more different from each other than those on land, species within marine invertebrate groups often look alike, leading to underestimates of their true numbers. Recent molecular and genetic studies have shown that described species frequently include several different, previously unrecognized species (*Knowlton, 1993*).

Major new groups of organisms are still being discovered in the sea, whereas this is rare on land. At least three new invertebrate phyla (the largest category of related organisms) and many major new groups (classes, orders, families, genera, which represent increasingly smaller groupings of related organisms) of deep-sea organisms, picoplankton, marine viruses, and archaeobacteria (a new kingdom of one-celled organisms that often live in extreme environments) have been described over the past 20 years. In the crustaceans, a new class, the primitive Remipedia, were discovered in caves in the Bahamas and described only in 1981. A new subclass of the Maxillopoda, the Tantulocarida (tiny ectoparasites of deep sea copepods, ostracods, and isopods) was erected in 1983. In the relatively well known malacostracan crustaceans, the Order Spelaeogriphacea was not discovered until 1957, the Order Amphionidacea recognized only in 1973, and the Order Mictacea established as late as 1985 (*Schram, 1986*). Crustacean biology, and marine biology in general, remains a realm of discovery.

Aquatic environments are difficult to see, sample, and study. The number of scientists who study invertebrates and the amount of scientific effort devoted to invertebrates other than insects is two orders of magnitude less than that devoted to vertebrates and one order of magnitude less than that devoted to plants (*Gaston and May, 1992*). In addition, tropical environments, far from the location of most biologists, have been much less studied than those at higher latitudes; 80% of ecological researchers are based in North America and Europe in comparison to 7% in Latin America and tropical Africa. Identification of species in aquatic habitats is further reduced because of the inability to observe them easily and the frequent requirement for Scuba diving and extensive logistic support.

Moreover, most crustacean and other aquatic taxa are small in body size. Many aquatic species live within crevices, holes, or burrows in coarse (rocks, coral, rubble) and level (mud, sand) substrata. Many are crepuscular or nocturnal to minimize fish predation (*Dominguez and Reaka, 1988*), making them difficult to see, collect, and study. Small organisms of

any environment always are poorly known and studied, but this is more extreme in aquatic environments, particularly in tropical marine environments, because of the remote localities and the difficult conditions for observing and collecting.

It seems likely that major advances in our knowledge of the extent of crustacean biodiversity will continue into the next centuries. These advances are imperiled, however, by a crisis in the number of systematists and taxonomists being trained (Feldmann and Manning, 1992; Reaka-Kudla *et al.*, 1997; Wilson, 1985). Although we know a fair amount about the morphology, ecology, behavior, life history, and development of many of the crustacean groups, we know astonishing little about the facets of their biology that are most critical for assessing their biodiversity status, particularly the distribution and abundance patterns of individual species and the life history features that render the species vulnerable or resistant to extinction. More distressing, we are incapable of determining these aspects of the biology of given taxa without a reliable foundation of systematics and taxonomy. The understanding and conservation of crustacean biodiversity will depend on the implementation of major new funding and training programs that are directed toward systematics and taxonomy, and toward natural history museums which hold the collections necessary for such comparative studies.

Ecology of the Arthropod Radiation

Between 3 and 4 billion years ago, biopolymers (proteins, polysaccharides, nucleic acids), which had been formed as a result of physical processes, became enclosed in membranes, and the resulting cells developed the ability to replicate themselves. These duplicated cells became organized into multicellular organisms that could move about on their own about a billion years ago. An accelerating explosion of biotic diversity occurred sometime in the Precambrian (perhaps 700–800 million years ago), but fossil remnants of this early proliferation are few, having been either poorly preserved or destroyed in subduction zones beneath migrating continents. By the beginning of the Paleozoic era (about 570 million years ago (mya)), almost all of the major phyla of animals already were present (by then being larger and more amenable to fossilization or preserved in continental rocks that are still available). The Cambrian marine environment (approximately 570–500 mya) was studded with sessile epibenthic forms such as stromatolites (aggregations of unicellular organisms, their secretions, and sand or other sedimentary particles); sponges and other now extinct spongelike forms; upright branched and laminar bryozoans (“moss animals”); filamentous now extinct organisms called graptolites, brachiopods (“lamp shells”), and other sessile organisms with ciliated feeding arms; various types of cnidarians (hydroids, anemones, primitive types of corals, jellyfish); stalked crinoids (sea lillies) and other primitive echinoderms; and the sessile life stages of primitive forms of chordates (our own ancient forebearers). Most of these sessile organisms fed on suspended particles near the seafloor.

Various other organisms crawled on the seafloor, many of them having developed segmentation (and other architectural features that allowed them to move more rapidly and feed

more effectively) as well as external armor that protected them from the increasing tendency for their ilk to eat one another. In addition to many lineages (often with bizarre features unlike any organisms known today) that perished in the race for motility and are known only as fossils, the motile benthic fauna included the early mollusks (whose followers would diversify during the Paleozoic into major grazers, suspension feeders, burrowing sediment feeders, and large extraordinarily active predators). Also present were diverse groups of early echinoderms (that would become grazers, burrowing sediment feeders, and slow-moving predators as the Paleozoic progressed) and the early filter-feeding chordates (many of which would develop into large, increasingly active and important predators as jawless and then jawed fish during the early to mid-Paleozoic). At least as important for biodiversity in the long run, the Precambrian benthic marine environment abounded with a diverse array of unsegmented and segmented worms that provided the prototype for the development of the joint-legged animals, the arthropods.

Whether the arthropod phyla (uniramians (centipedes, millipedes, insects), onychophorans, tardigrades, chelicerates (horseshoe crabs, scorpions, spiders, ticks), pycnogonids, trilobites, pentastomids, and crustaceans) arose from only one group or independently from several groups of the early segmented annelid worms is hotly debated. The annelids and arthropod groups originated in the Precambrian, and all of the major phyla were distinct by the time they were fossilized. The crustaceans, trilobites, and chelicerates appeared first in the fossil record, followed at a later time by the uniramians. Some experts have concluded, on the basis of functional morphology and developmental patterns, that the major arthropod groups probably all arose independently, and that the Crustacea are not closely related to the uniramians, trilobites, or chelicerates. Other scientists have argued, on the basis of morphology, that the trilobites are ancestral to both the chelicerates and crustaceans. New evidence from RNA and DNA sequences has brought forth various views, including the idea that the crustaceans are more closely related to the uniramians than to other arthropod groups. The question of how the arthropod groups evolved, then, remains far from solved at present.

Many workers concur that the onychophorans (velvet worms) and the uniramians have a common origin. Some workers have suggested a possible connection between two Cambrian marine fossils and the onychophorans, who are represented today by 80 species in warm moist terrestrial environments. The first myriapods (centipedes, millipedes) were fossilized in the Silurian (440–405 mya) and probably they or their ancestors were marine. Terrestrial myriapods and wingless insects are known from the Devonian (405–360 mya), and winged insects had arisen by the Carboniferous (360–290 mya). These underwent a continuing spectacular radiation that resulted in almost a million species of described insects that inhabit almost all terrestrial and many aquatic environments today. In addition to 32 living orders of insects, at least 10 other orders arose and went extinct in the late Paleozoic and early Mesozoic.

About 400 species of tardigrades (water bears) are known from marine (intertidal to deep-sea) environments, freshwater, hot springs, and semiterrestrial environments in plants

and humus; the most primitive group is marine. A single fossil is known from Cretaceous (135–65 mya) amber. These minute organisms (most 0.1–0.5 mm, a few to 1.7 mm) occupy benthic, interstitial, water film, commensal, and parasitic habitats. They also have been collected from some of the driest habitats on earth, the Antarctic dry valleys; they are capable of being freeze-dried, after which they resume metabolism when rehydrated.

Represented by the xiphosurans (horseshoe crabs) and the eurypterids (sea scorpions), the early chelicerates were marine and had appeared by the Cambrian. Eurypterids and xiphosurans were crawling scavengers and predators, crushing food between the bases of their legs. The anterior appendages (cheliceræ) of some eurypterids were well developed and clawed. Many eurypterids were small but some grew to very large sizes (up to 3 m). These marine forms flourished during the Ordovician, Silurian, and Devonian (500–360 mya) and were abundant until the Permian (290–245 mya), after which the eurypterids became extinct and the xiphosurans were greatly diminished (only five species of horseshoe crabs remain today). Some eurypterids apparently invaded fresh water and may have become semiterrestrial. Related lineages, including the scorpions (the most primitive living arachnids) were present in the Silurian and invaded land very early, at least by the Carboniferous. Diversification of the Chelicerata resulted in a total of about 80,000 described, mostly terrestrial species living today.

The pycnogonids (sea spiders), considered a sister group to the Chelicerata, are known from the Devonian onward. They are represented by about 1000 species and 86 genera today, all marine. They are suctional predators and occupy all oceans down to about 7000 m. Most are small (<10 mm), though the bodies of some deep sea forms are 20 to 30 mm with leg spans of up to 700 mm. The “protonyphon” larva of some pycnogonids and the “trilobite” larva of some xiphosurans share some developmental features with the “protaspid” larva of trilobites.

The trilobites, along with the chelicerates, were major components of the motile benthic fauna of the early Paleozoic. The trilobites were exceedingly abundant during the Cambrian and Ordovician (600–440 mya) and persisted in somewhat lower numbers until the end of the Permian (245 mya), after which they became extinct. All of the 4000 species were marine. They were major scavengers and predators, crushing food between the bases of their legs, which operated as gnathopod jaws. Some were possibly sediment or suspension feeders. Most species were small (10–30 mm), some were moderately sized (30–60 mm), and a few giants (600–700 mm) are known. Most species were benthic and epifaunal or shallow infaunal, but some small (<10 mm) forms were planktonic.

The pentastomids, wormlike parasites that inhabit the respiratory system of terrestrial vertebrates, include about 95 species and are thought to be related to crustaceans. They may have been a relatively late offshoot of early arthropod lineages, developing with or after the radiations of terrestrial vertebrates in the Carboniferous (amphibians), Permian (reptiles), and Mesozoic (reptiles, birds, mammals).

In the midst of this evolutionary theater rose the crustaceans. We shall return to the historical development of

crustacean diversity after we are introduced to the major characters.

Biodiversity of Fossil and Modern Crustacea

The Major Groups of Crustacea

Centers of Taxonomic Diversity

At least five major radiations in ancestral crustacean lineages produced the remipedes, cephalocarids, branchiopods, maxillopods, and malacostracans (Table 1). Scientists believe, either because of their primitive body forms or their fossil record, that all five major groups have ancient origins extending back at least as far as the beginning of the Paleozoic. The remipedes, cephalocarids, and branchiopods probably are impoverished relicts of ancient great lineages that did not fossilize well. Today, however, these three groups (along with a number of primitive malacostracan lineages) are marginalized in hypersaline, brackish, and fresh water (sometimes hot springs or ephemeral pools), caves, groundwater, or other isolated, seemingly suboptimal habitats. Collectively, these three classes contribute only 14% of the diversity in orders, 5% of the diversity in families, 2% of the generic diversity, and 2% of the species diversity within modern crustaceans. The remaining 2 classes—the maxillopods and especially the malacostracans—are the dominant groups in most major marine environments today and are responsible for much of the diversity in major body plans (e.g., as represented in subclasses; Table 1). The malacostracans alone constitute over half (53%, 59%, and 55%) of all present and past (fossilized) crustacean families, genera and species, respectively. The major groups of malacostracans have been subject to considerable turnover in the fossil record, however, since the lineage is ancient and many of their major evolutionary experiments (body plans at the level of order) have been lost to extinction. Whereas 80 to 100% of all the orders of branchiopods and maxillopods ever known are still extant, only 59% of malacostracan orders are still living. If their order did survive background extinction and the great mass extinctions (e.g., at the ends of the Paleozoic and the Mesozoic), however, malacostracan families have persisted (or are currently diversifying) at a higher rate (88% of all known families are still extant) than those of the maxillopods (76% living) and branchiopods (74% extant). Though only 87% of branchiopod genera still exist, very high percentages of genera in both the malacostracans (97%) and maxillopods (96%) are alive today.

Within the maxillopods, centers of taxonomic diversity are found in the copepods, ostracods (seed shrimp), and, to a lesser extent, cirripeds (barnacles). Copepods include 38% of the orders, 50% of the families, 54% of the genera, and 49% of the species in the maxillopods. Ostracods constitute 29% and 38% of the orders and families, and 36% and 44% of the genera and species in the maxillopods. Barnacles comprise 19% and 11% of the orders and families, and 10% and 6% of the genera and species in the group. Both ostracods and barnacles are ancient lineages whose fossil records extend back at least to the dawn of the Paleozoic.

Within the malacostracans, peracarids and eucarids dominate the group in terms of taxonomic diversity. Peracarids

Table 1 Minimum numbers of taxa for the five major crustacean evolutionary radiations

<i>Class</i>	<i>Subclasses</i>	<i>Orders</i>	<i>Families</i>	<i>Genera</i>	<i>Species</i>
Class Remipedia	—	2 (1 living), 4%	1 (1 living), 0.1%	6 (5 living), 0.1%	11 (10 living), <0.1%
Class Cephalocarida	—	2 (1 living), 4%	2–3 (1–2 living), 0.2%	At least: 5 (4 living), 0.1%	At least: 11 (10 living), <0.1%
Class Branchiopoda	—	4–5 (4 living), 7%	At least: 35 (26 living), 4%	At least: 108 (94 living), 2%	At least: 836 (821 living), 2%
Class Maxillopoda	6 living	21 (18 living), 38%	355 (270 living), 43%	At least: 2162 (2077 living), 39%	At least: 18,388 (18,293 living) 43%
	Ostracoda	6 (3 living), 29%	136 (55 living), 38%	At least: 776 (695 living), 36%	At least: 8081 (about 8000 living), 44%
	Mystacocarida	1 living, 5%	1 living, 5%	2 living, 0.1%	10 living, 0.1%
	Copepoda	8 living, 38%	177 living, 50%	1167 living, 54%	About 9000 living, 49%
	Branchiura	1 living 5%	1 living, 0.3%	4 living, 0.2%	150 living, 1%
	Tantulocarida	1 living, 5%	1 living, 0.3%	2 living, 0.1%	5 living, <0.1%
Class Malacostraca	Cirripedia	4 living, 19%	39 (35 living), 11%	At least: 211 (207 living), 10%	At least: 1142 (1138 living), 6%
	2–7 (usually 5) living	27 (16 living) (3 extinct groups unassigned to sub-classes), 48%	413 (383 living), 53%	At least 3175 (3093 living), 59%	At least: 23,890 (23,800 living) 55%
	Phyllocarida	5 (1 living), 19%	13 (2 living), 3%	At least: 55 (5 living), 2%	At least: 65 (13 living), 0.3%
	Hoplocarida	3 (1 living), 11%	At least: 19 (13 living), 4%	At least: 78 (68 living), 2%	At least: 413 (400 living), 2%
	Syncarida	3 (2 living), 11%	10 (6 living), 2%	At least: 37 (33 living), 1%	At least: 119 (115 living), 0.5%
	Peracarida	10 (9 living), 37%	268 (255 living), 62%	At least: 1793 (1775 living), 56%	At least: 12,726 (12,706 living), 53%
Class Malacostraca	Eucarida	3 living, 11%	121 (107 living), 28%	At least: 1213 (1212 living) (fossils mostly not quantified), 38%	At least: (10,567 living) (fossils mostly not quantified), 44%
	Totals	—	56–57 (40 living)	At least: 824 (681 living)	At least: 43,136 (42,934 living)

In cases where number of taxa is controversial, the lower number was used in the total. In many cases, the number of certain taxa (especially genera and species) were not summarized in sources, so minimum numbers were estimated from the number of higher taxa (e.g., in a group with five families for which data on number of genera were not summarized, it was assumed that at least five genera (one per family) and at least five species (one per genus) were present). Therefore, these data probably considerably underestimate the number of genera and particularly the number of species in these classes (although total species exceed those previously estimated by other authors, e.g., Brusca and Brusca; 1990, who did not include paleontological data). Percentages horizontally aligned with classes (bold) represent the total number in that taxon compared to the number for all Crustacea. Percentages horizontally aligned with subclasses (not bold) represent the total number in that taxon compared to the total number in that class. Percentages are based on total (fossil and living) taxa and are rounded to the nearest whole number (except when <1%).

include 37% of the orders and 62% of the families, and at least 56% of the genera and 53% of the species, in the Malacostraca. The eucarids make up only 11% of the orders and 28% of the families, but at least 37% of the genera and 44% of the species within the group.

Architectural Diversity

To understand the diversity of Crustacea, it is necessary to come to grips with their major ways of life as reflected in their body plans. The range of morphological diversity among crustaceans is remarkable, considerably greater than that of the insects. Primitively, each segment supported a pair of appendages. Crustacean appendages have multiple joints along their length and are considered to have evolved from a biramous condition (divided into two branches), although

both head and trunk appendages have lost one side of the branch in some groups. The primary mode of evolutionary change in the early diversification of crustaceans was by molding segments into functional units along the length of their body and reducing various morphological features, including both segments and appendages. The resulting fundamental body regions included a five segmented head (cephalon) and a long, segmented trunk that is usually divided into a thorax and abdomen.

The head was formed by telescoping five segments and their associated appendages into a fused unit that bears two pairs of antennae (a distinguishing characteristic of crustaceans), the mandibles (jaws) that flank the mouth, and two pairs of accessory food handling appendages, the maxillules and maxillae. The antennules (first pair of antennae) are

biramous in the primitive remipedes. However, the antennules are uniramous in the cephalocarids, all of the branchiopods, all of the maxillopods (where present), and some of the eumalacostracans, while those of the primitive phyllocarid malacostracans and some of the eumalacostracans are biramous and those of stomatopods triramous, raising the question of whether or not the antennules of crustacean ancestral groups all were biramous. The antennules are reduced or lost in the parasitic branchiurans and tantulocaridans and in many sessile adult cirripeds. The second antennular appendages (antennae) are biramous in most crustaceans but are uniramous in anostracans, some copepods, leptostracans, some but not other fossil phyllocarids, and some eumalacostracans. The antennae are reduced in the parasitic branchiura (modified for attachment) and lost in the notostracans, tantulocarids, and sessile adult cirripeds.

One or more of the anterior thoracic segments may be fused to the head (remipedes, isopods, amphipods), or the anterior thoracic appendages (maxillipeds) may be functionally associated with the mouthparts of the head (fossil kazacharthran branchiopods; fossil lipostracans; ostracod, mystacocaridan, and copepod maxillopods; stomatopod and possibly palaeostomatopod hoplocaridans; anaspidacean syncarids; mysidan, lophogastridan, tanaidacean, spelaogrighacean, cumacean, mictacean, isopod, and amphipod peracarids; stomatopods and many eumalacostracans).

Reflecting very early divergence among groups of crustaceans, the division of the trunk into units that functioned in feeding (the anterior appendages), reproduction, and locomotion (often with accessories that aided respiration) was much more variable among major crustaceans groups than the head region. The wormlike remipedes usually are considered to represent the most primitive crustacean morphology. Their oarlike appendages are undifferentiated throughout the long trunk, followed by an anal segment with simple caudal rami. The trunk of the cephalocarids, however, is divided into 8 thoracic segments, 11 abdominal segments, and an anal segment with caudal rami. The trunk region of both the branchiopods and maxillopods is variable among groups. Several groups with modified morphology possess simply a reduced trunk (cladocerans, conchostracans, ostracods, mystacocarids, and adult tantulocarids). A thorax is present in the anostracans and notostracans (usually 11 segments), extinct kazacharthrans, copepods (6 segments), branchiurans (4 segments), tantulocaridans (6 segments in juveniles), cirripeds (6 segments, reduced), and malacostracans (8 segments). The number of segments included in the abdomen is variable within several groups of branchiopods (anostracans, notostracans, fossil kazacharthrans, conchostracans) and in juvenile tantulocarids and ascothoracidan barnacles. The abdomen is reduced or lost, or segmentation obscured, in groups that are modified for specialized ways of life (cladocerans, the parasitic branchiurans and tantulocaridans, and most cirripeds, especially the parasitic forms). The primitive phyllocarid malacostracans all possess an abdomen with seven segments, in addition to a terminal anal segment with caudal rami. Adult hoplocaridans and eumalacostracans have lost one of the abdominal segments, however, and bear six abdominal segments plus an additional flattened anal segment termed a telson. Morphological and developmental evidence of a

vestigial seventh abdominal segment (either at the front or the posterior of the abdomen) in the stomatopod hoplocaridans and in the mysidan, tanaidacean, and possibly the isopod eumalacostracans reflects another evolutionary tendency toward reduction of segments.

Trunk appendages in the remipedes are oarlike but different from the leaflike or phyllopodous appendages of the primitive branchiopods. Leaflike or phyllopodous appendages predominate in the cephalocarids, all of the branchiopods, and in the primitive malacostracans, including a number of extinct groups and the modern leptostracans. However, greatly modified or reduced numbers of trunk appendages (especially on posterior trunk segments) characterize the maxillopods (e.g., the ostracods, mystacocarids, and copepods). Parasitic forms (e.g., the adult rhizocephalan barnacles) often lose all appendages. The copepods, branchiurans, and juvenile tantulocarids all have biramous thoracic legs. In the malacostracans, however, some of the thoracic appendages are uniramous and some biramous in stomatopods, and all eight pairs of the thoracopods usually are uniramous (with some of these enlarged and clawed) in the eumalacostracans. Even some of these groups, however, show reduction in development of appendages toward the posterior of the thorax. Branched or layered structures arising from the base of the thoracic legs (epipods) serve as gills in the hoplocaridans and eumalacostracans.

Posterior trunk or abdominal appendages are reduced in most cephalocarids, branchiopods, and maxillopods (notostracans, conchostracans) or absent (cephalocarids, anostracans, cladocerans, ostracods, mystacocarids, copepods, branchiurans, tantulocarids, and cirripeds). Like the remipedes, however, most of the malacostracans bear pleopods on the abdomen that often function in swimming (and sometimes facilitate mating). These may be present or absent in different fossil phyllocarids and are present, but reduced toward the posterior, in the leptostracans. Hoplocarids have five pairs of well-developed pleopods that support tufted gills (palaeostomatopods, stomatopods). Some peracarid eumalacostracans (isopods) also bear breathing structures (gills or tracheae) on their pleopods. The eumalacostracans have pleopods, but their number and size often is reduced (particularly toward the posterior) or may be absent (anaspidaceans, some mysidans, some thermosbaenaceans, some cumaceans, and some anomurans). The sixth abdominal segment is fused to the telson in modern (but not ancient) tanaidaceans, as well as some cumacean and isopod eumalacostracans. The hoplocaridans and most groups of eumalacostracans have a well-developed "tailfan" that is composed of uropods (bladelike appendages on the sixth abdominal segment) and a telson (a flattened and often armored posterior segment that may have one or more terminal projections but never bears caudal rami).

The position of the gonadal duct openings (gonopores) on either the ventral part of the body or the bases of the legs varies consistently among groups of crustaceans, reflecting the ancient divergence of different taxa. The female gonopore opens on the sixth thoracic segment, and the male gonopore on the eighth thoracic segment, in all malacostracans.

Both simple (ocelli) and compound (faceted) eyes are present in most taxa. One medial ocellus frequently occurs in larvae, and one or more ocelli are found in adults of some

groups of branchiopods and maxillopods such as the anostracans, notostracans, cladocerans, ostracods, mystacocarids, copepods, and branchiurans. Only ocelli (or ocellus-like structures) are present in the adults of the extinct kazacharthrans, some cladocerans, mystacocarids, and copepods. Compound eyes often are positioned on stalks, as in the anostracan branchiopods, most malacostracans, including many phyllocarids (extinct canadaspidans, leptostracans), the hoplocarids (extinct aeschronectids, stomatopods), extinct belotelsonideans, and most eumalacostracans (extinct palaeocaridaceans, some anaspidaceans, mysidans, lophogastriidans, thermosbaenaceans (nonfunctional), some tanaidaceans (on lobes), spelaeogriphaceans (on lobes), cumaceans (on a medial lobe), mictaceans (nonfunctional on lobes), some isopods (on lobes), euphausiaceans, amphionidaceans, dendrobranchiate shrimps, procaridid shrimps (reduced), carideanshrimps, stenopodidean shrimps, thalassinidean shrimps, astacideans, palinurans, anomurans, and brachyurans). Eyes are reduced or absent in members of primitive lineages, sessile lineages, or species that inhabit caves or the deep sea (the remipedes, cephalocarids, many ostracods, tantulocarids, adult cirripeds, tanaidaceans, some spelaeogriphaceans, many cumaceans (especially females), some mictaceans, some isopods, some amphipods, amphionidaceans, procaridid shrimps, some caridean shrimps, some stenopodid shrimps, and some astacideans). The branchiuran maxillopodans have a particularly intriguing pair of compound eyes that project internally into a blood sinus suspended on a stalk composed of the optic nerves. Muscles move the eyes within the blood sinus.

Either a cephalic shield or a carapace may cover the head and part or all of the thorax. Remipedes, cephalocarids, copepods, and tantulocarids bear a cephalic shield, while a “folded” or “bivalved” carapace characterizes the notostracans, extinct kazacharthrans, cladocerans, conchostracans, ostracods, branchiurans, cirripeds, phyllocarids, hoplocaridans, and most eumalacostracans. However, these structures are reduced or absent in other groups (anostracans, mystacocaridans, syncarid and most peracarid eumalacostracans). The carapace of cirripeds is modified into a fleshy, saclike mantle that may envelope most of the body and, in thoracicans, is covered with calcareous plates; eggs are brooded in the mantle cavity for various lengths of time. Conchostracans, most cladocerans, and some ostracods use their carapace as a brood chamber; one cladoceran broods eggs in its molted carapace. Thermosbaenacean females possess a very enlarged, thin, blood-filled carapace that functions both as a brood chamber and for gaseous exchange. The enlarged, very thin carapace in female amphionidaceans may serve a similar function, though this has not yet been examined. The carapace extends laterally in decapods to enclose the base of the legs and gills, increasing the efficiency of water flow over the gills.

The Rise of Crustacean Diversity in the Fossil Record

All of the early continents, including Gondwana (modern South America, Africa, Madagascar, India, Australia, Antarctica), Baltica (Scandinavia and northwestern Europe), Laurussia (North America), Siberia, Kazakhstania, and China,

girdled the earth in tropical and subtropical locations. No land extended above 60° N or below 60° S during the Cambrian (570–500 mya), allowing mild warm conditions in most coastal areas. Developing from segmented wormlike forms, the earliest crustaceans must have developed sets of pronglike or leaflike legs to shuffle along the surface of the soft marine sediments. In addition, they secreted a tough, often calcified cuticle to protect them from the other benthic predators (nautiloid molluscs and trilobites, which were the most abundant benthic predators and scavengers in most marine habitats during the Cambrian). The earliest fossilized crustaceans included three orders of phyllocarid malacostracans (phyllopodous detritus feeders, scavengers, and generalized predators known from the Lower Cambrian); the thoracican goose barnacles (suspension-feeding maxillopods known from the Middle Cambrian); and the ostracods (scavenging, detritus-feeding maxillopods known from the Cambrian onward). Following the recent discovery of the predaceous Remipedia, which exhibit a very primitive arrangement of segmentation and appendages, many workers concluded that the remipedes, though not readily fossilized, represent one of the probable forms of the earliest crustaceans and likely were present in the Cambrian. In addition, the primitive morphology of the ascothoracidan barnacles suggests that they also may have been present (though unfossilized) in the very early Paleozoic. Of these early groups, the canadaspid phyllocarid malacostracans did not persist into the Ordovician.

During the Ordovician (500–440 mya), part of the huge island continent of Gondwana slipped beneath what was then the south pole, but the climate remained generally warm and mild, with the northern reaches of Gondwana and most of the island continents situated in tropical or subtropical waters. Xiphosuran (horseshoe crabs) and eurypterid (sea scorpions) chelicerates joined the exceedingly abundant, ravenous trilobites on the seafloor. Nautiloids continued to diversify morphologically; jawless fish (encased in protective outer layers of bone and still not very motile) proliferated. The ostracod crustaceans underwent their greatest radiation, and phyllocarid malacostracans (hymenostacans, archaeostacans) were abundant; the hymenostacans, however, disappeared after the Ordovician. A mass extinction closed the Ordovician.

The Silurian (440–405 mya) also was characterized by mild climates (except in the parts of Gondwana that rested over the pole), and a circumtropical current wound its way among the island continents and reefs composed of stromatoporoid sponges, rugose corals, and other sessile fauna. Eurypterids flourished, trilobites persisted in lesser numbers, myriapods and primitive arachnids (probably marine) arose, and jawed fish made their appearance. Thoracican goose barnacles (attached to a eurypterid) are recorded, ostracods flourished, and archaeostacan phyllocarid malacostracans were abundant.

During the Devonian (405–360 mya), predation from the flourishing eurypterids, increasingly motile jawed fishes, and nautiloid cephalopod mollusks dominated benthic ecology. Trilobites still occupied many benthic marine environments. Pycnogonids were present. In an era of mild climates and inland seas, fish and invertebrate groups radiated into freshwater environments. A circumtropical current coursed between Gondwana and the island continents. It was in these

warm, sheltered, shallow coastal waters laden with archipelagos that crustaceans began their great radiations. The fossil record shows that the archaeostracans (phyllocarid malacostracans) reached their greatest diversity, and the predaceous hoplocarids (palaeostomatopods, archaeostomatopods) made their first appearance. The ostracods began their second great radiation. The boring acrothoracican barnacles and the first predaceous, lobster-like decapod malacostracans appeared (*Palaepalaemon*, allied either to the astacid crayfish and lobsters or palinurid lobsters). Detritus-feeding and scavenging conchostracan branchiopods originated, invading fresh water, and the detritus-feeding lipostracans (allied to the cephalocarids or branchiopods) flourished in hot springs. Fossils and primitive morphology suggest that other primitive detritus-feeding branchiopods (notostracans, anostracans) likely were present too. Another mass extinction impacted faunas during the Late Devonian.

The taxonomic, morphological, and ecological diversification of the Crustacea accelerated during the Carboniferous (Mississippian, Pennsylvanian; 360–290 mya) of the Late Paleozoic as the marine chelicerates and trilobites began their decline. The continents were beginning to congeal, setting the stage for the global climatic changes that likely contributed to the greatest mass extinction of all time at the end of the Paleozoic. Gondwana had largely completed its migration beneath the south pole and emerged to begin to fuse with Laurussia and Baltica (modern North America, Scandinavia, and northwestern Europe) over the equator. Though the southern reaches of Gondwana (modern South America) were still plagued with bouts of glaciation, the warm moist equatorial continents were awash with inland seas and swamps. Land plants had multiplied in diversity and biomass, their seed ferns, scale trees, and conifer trees producing great forests that decayed in coal swamps or washed out onto the continental shelves, enriching coastal sediments. Insects took flight (including some huge species), amphibians underwent their greatest radiation, and the first reptiles appeared. Marine organisms proliferated in the enriched coastal sediments. Sharks and jawed bony fishes were abundant and active. Nautiloids declined, replaced by the emerging ammonoid cephalopod mollusks. Remipede crustaceans are recorded from the Lower Pennsylvanian. Conchostracan branchiopods radiated anew. Notostracan branchiopods probably were present. Acrothoracican barnacles are known from their borings in clam shells, and lepadomorph thoracican barnacles are recorded from this period. Early malacostracan lineages (the scavenging archaeostracan and hoplostracan phyllocarids; the scavenging aeschronectids and predaceous hoplocarids; the scavenging belotelsonidans, waterstonellideans, eocaridaceans, and paleocaridaceans) were exceedingly abundant and dominated the shallow marine fauna. Pygocephalomorph and lophogastridan mysidaceans came on the scene, as well as most of the peracarid malacostracans (tanaidaceans, spelaegriphaceans, cumaceans, isopods, and probably other unfossilized groups). Definitive palinuran decapods appeared, and the earliest lineages leading to the brachyuran crabs evolved. Several of the early malacostracan groups (hoplostracan phyllocarids, aeschronectid and palaeostomatopod hoplocarids, belotelsonids) disappeared after the Carboniferous as the peracarid and eucarid malacostracans took center stage.

The Permian period (290–245 mya) brought one of the most significant geomorphological events in the history of the earth. All of the previous continental landmasses fused into a single gigantic continent, Pangaea, between 260 and 250 mya. The collision of Gondwana, Laurussia, Baltica, Kazakhstan, and Siberia is still visible in the mountain belts stretching across northern South America, northwestern Africa, eastern North America (the Appalachians), Britain and Scandinavia, and Eurasia (the Urals and other ranges). By 250 mya, the ancient island continent of China also had joined the supercontinent. Pangaea now straddled the equator, anchored by Siberia near the north pole and Antarctica over the south pole. The circumtropical seaway was closed. The elevated landmasses produced a more extreme, cooler, continental climate than had been present throughout most of the Paleozoic (whether or not this was solely responsible for the mass extinctions is debated). In the cool, dry conditions, reptiles radiated, replacing the previously dominant amphibians, and the first mammal-like reptiles appeared. Many organisms, including worms, heart urchins, sea cucumbers, and crustaceans, mined the organic riches in the coastal sediments, throwing up sediment that buried and clogged the feeding structures of the epibenthic sessile filter feeders. Conchostracan branchiopods, ostracod maxillopods, primitive malacostracans (archaeostracan phyllocarids, the first leptostracan phyllocarids, waterstonellideans, eocaridaceans, palaeocaridacean syncarids, and pygocephalomorph mysidaceans), at least several peracarid malacostracans (tanaids, cumaceans, isopods), and the first definitive astacid (crayfish- or lobster-like) eucarid malacostracans thrived in benthic marine environments. Brachyurans likely were present. The Paleozoic era ended, however, with the loss of 96% of all species. Many crustacean groups did persist through the Permo-Triassic biotic catastrophe, though, and underwent reradiation during the Mesozoic.

The early Triassic was a relatively barren environment both on the land and in the sea. The landmasses were high, cool, and dry, with widespread deserts. In coastal waters, no corals or reef communities are known. All of the trilobites, eurypterids, most of the nautiloid cephalopods, and many of the primitive fishes had been lost. All of the primitive phyllocarid malacostracans, except for the newly evolved leptostracans, were gone. All of the early hoplocarids had been eliminated except for a thin line, probably present but not fossilized, that would lead to the modern stomatopods. All of the late Paleozoic primitive malacostracans (the belotelsonids, waterstonellideans, eocaridaceans, the early palaeocaridacean syncarids, the pygocephalomorph mysidaceans) were now absent. The sessile epibenthic suspension feeding community (many of the bryozoans and brachiopods, many primitive echinoderms such as blastoids and most of the crinoids, primitive tabulate, and rugose corals) that had dominated Paleozoic benthic habitats had been largely obliterated. Most of the plankton was gone. As the Triassic progressed, however, mammal-like reptiles and the early groups of dinosaurs appeared, other reptiles diversified, and coniferous trees came to dominate the land. In the sea, the surviving remnants of the cephalopods began to diversify into modern groups, including predaceous squid- and octopus-like forms. Scleractinian corals began to proliferate, even though they were subordinate to

sponges, algae, and bryozoans as reef builders. Conchostracan branchiopods, ostracods and lepadomorph cirripeds, anaspidean syncarids, lophogastrid mysidaceans, tanaid and isopod peracarids, the first dendrobranchiate decapod shrimps, and astacid and palinurid decapods are recorded. Probably many more lineages were reestablishing themselves, though unfossilized, during this period (remipedes, cephalocarids, all of the branchiopod groups, many of the primitive maxillopods, other primitive eumalacostracans such as syncarids, and the mysidaceans, peracarids, and eucarids). Another mass extinction, however, spread biological devastation in the Late Triassic.

It is thought that huge continental landmasses begin to accumulate heat beneath them, creating convection currents in the mantle that cause landmasses to drift apart approximately every 500 million years. In the Jurassic (210–140 mya), Pangaea began to break apart. About 200 mya, Laurasia (North America and Eurasia) moved away from Gondwanaland, forming a nascent Atlantic Ocean in the west and a gulf between Asia and East Africa in the east. India drifted away from Antarctica toward Asia, and the south Indian Ocean began to form between Australia (still attached to Antarctica), Antarctica, and the joined southern tips of Africa and South America. A widening rift between South America and Africa was flooded with seawater near the end of the Jurassic. The northern drift of Laurasia created a pathway for a circum-tropical current between the northern and southern continents. This shallow warm seaway, adorned with archipelagos, would be called the Tethys Sea, and it was the cradle from which most of the modern families of organisms that we know today would emerge.

The early Jurassic climate was cool, becoming warmer. High sea levels encroached on the continents, spreading shallow seas. Although mass extinctions challenged the faunas during the Middle and Late Jurassic, the Jurassic period is known for its spectacular radiation of reptiles, including the dinosaurs and pterosaurs. Modern groups of amphibians (frogs, salamanders) and birds arose. Primitive flowering plants and many of the modern groups of insects (flies, moths, bees, wasps, ants) diversified in the increasingly warm, mild climate. In the sea, marine reptiles must have been fearsome predators, crocodiles and turtles abounded, many of the modern families of boney fish were formed, corals acquired symbiotic algae that allowed them to grow up and away from sedimentation (such as that created by burrowing animals in the late Paleozoic) 10 times faster than they could in the absence of the photosynthetic symbiont. Reefs became more extensive and boring organisms more common. The Jurassic fossil record of Crustacea includes conchostracan and notostracan (extinct Kazacharthrans) branchiopods, and shows a renewed ostracod radiation. The lepadomorph barnacles were present, and the balanomorph (acorn) barnacles made their first appearance. Many of the other groups (remipedes, cephalocarids, other branchiopods, other maxillopods) likely were present but not fossilized. In the Malacostraca, the fossil scudid hoplocarids (descendents of the Devonian archaeostomatopods and progenitors of the modern stomatopods) arose. The last remaining vestige of the phyllocarids (the leptostracans) and some syncarids may have been present but not fossilized. The first mysidacean eumalacostracans appeared,

tanaid and isopod peracarids were present, and many of the other peracarids likely were present but not preserved. The eucarid malacostracans burst on the scene, as shown by the first appearances of fossil caridean, stenopodidean, and thalassinidean shrimps, and anomuran and definitive brachyuran crabs. Dendrobranchiate shrimps, as well as astacidean and palinuran crayfishes and lobsters, also were present in the fossil record, completing the roster of all the major groups of eucarids known today. Despite the mass extinctions, no major lineages were lost during the transition from the Jurassic to the Cretaceous.

The tropical Tethyan seaway continued to girdle the earth and maintain mild conditions during the Cretaceous (140–65 mya), although the pathway was narrowing in several sites (e.g., northeastern and northwestern Africa). North America was still united with Eurasia despite a widening gulf invading northward from the opening Atlantic. India had not yet crashed into Eurasia, Madagascar was sliding northeastward from southern Africa, and Australia had begun to separate from Antarctica, beginning its trek toward the tropics. Africa and South America had left Antarctica behind as they migrated northward and severed their connections to each other. The Andes and Rocky mountains rose as North and South America ploughed westward and the Pacific plates dived beneath them. The continents were awash with spreading inland seas and swamps. The reptilian radiation was at its apex, spawning the largest land and marine reptiles ever known. Grasses appeared, and other flowering plants and insects diversified even further; coniferous gymnosperms declined.

In the sea, reefs began to accrete and proliferate on an unprecedented worldwide scale and reached their highest diversity ever. Scleractinian corals flourished, and in sheltered areas huge rudist bivalve mollusks (which, like the corals, may have obtained photosynthetic symbionts) committed massive deposits of calcium carbonate to reef structure, threatening the dominance of corals in the reef community. The teleostean (boney) fishes underwent major diversification, developing new body shapes that increased their maneuverability, calcareous mouth plates that crushed shelled and hard-bodied prey, and pincer-like jaws that could grab and pluck prey from the substratum. Benthic octopuses with flexible arms and bodies could engulf and subdue prey. Crustaceans developed hardened specialized claws that could crush or cut prey. Motile and sessile organisms seeking refuge from the burrowing organisms that caused extensive movement of benthic sediment (bioturbators) likely colonized the high, hard substratum provided by the corals and rudists. Boring organisms proliferated worldwide, for boring into the calcareous substratum provided protection from the increasingly diverse and dangerous predators. Individual bioeroders eventually died, however, leaving a vacant crypt. This three-dimensional microenvironment provided a safe refuge for a multitude of small sessile and motile invertebrates. The organisms that invaded the holes left by the borers, termed the cryptofauna, were constrained to small body sizes in order to occupy the protective holes, were plagued by predation whenever they emerged from the crevice to feed or mate, and had to develop special adaptations for acquiring and keeping the packed refuge space. All of these processes accelerated morphological and other adaptations in the benthic fauna. Small body size

usually is associated with production of fewer, larger eggs, abbreviated development, and higher rates of speciation and extinction in motile invertebrates. These life history features likely facilitated diversification of other behavioral and morphological features, such as the deadly fighting behavior and armored bodies and appendages that developed in many of the stomatopods and decapods. Special adaptations (including coloniality, unique growth strategies, and chemical warfare) also developed in the sessile cryptofauna, promoting diversification and enabling them to better acquire and defend living space.

Among the crustaceans, the conchostracan branchiopods and ostracod maxillopods again are represented in the Cretaceous fossil record; the remipedes and all other modern groups of branchiopods and maxillopods likely were present but not preserved. Copepods, ascothoracidan barnacles (as trace fossils), verruciform (wart) barnacles, and the squat modern cthamaleid acorn barnacles made their first appearance as fossils. Among the lower malacostracans, the leptostreacan phyllocarids likely were present but unfossilized, and the predaceous stomatopod hoplocarids came into their own. The extinct scudids (bathysquilloids) and three of the major modern groups of stomatopods (the reef-dwelling gonodactyloids, mud-burrowing squilloids, and sand-burrowing lysiosquilloids) all appeared for the first time. The syncarids and mysidaceans probably were present but not recorded. Although their distribution suggests a more ancient derivation, the thermosbaenaceans are first known in the Cretaceous. Other peracarids and other eucarid shrimps (stenopodideans, thalassinideans) probably were present, but the tanaidaceans and isopods, as well as the dendrobranchiate and caridean shrimps, definitively inhabited Cretaceous seas. The advanced eucarids (astacids, palinurans, anomurans, brachyurans) were all present and continued their radiations begun in the Jurassic.

Following a mild mid-Cretaceous mass extinction, a significant mass extinction at the end of the Cretaceous eliminated the dinosaurs and many of the great reptiles (including the huge flying and marine reptiles), the ammonoids and many of the older cephalopod lineages, the reef-building rudist bivalves, and many groups of plankton. It is likely that the explosive impact of a giant asteroid contributed to this biotic disaster. The role of additional factors in the faunal turnover between the Mesozoic and the Cenozoic is debated. Mass extinctions often determine the biotic structure of the next era by filtering what major groups survive to radiate again in the postextinction periods. This was true for the mammals and birds, relatively minor groups in the Mesozoic that persisted through the mass extinction and then, in the absence of the great reptiles, diversified and dominated the ecology of terrestrial environments in the Cenozoic. For the crustaceans, however, the biotic upheaval at the end of the Mesozoic had far less impact than had the great extinction at the end of the Paleozoic. The kazacharthran branchiopods, related to the notostracans, had been lost during the Jurassic, but the lineage continued and survives today. The hoplocarids also persevered. Despite the possible loss of the scudid stomatopods at the end of the Cretaceous, the bathysquilloid lineage persisted (though restricted today to deep continental shelf environments). The new stomatopod superfamilies generated in

the Cretaceous endured and are common in warm shallow waters today. No other major crustacean lineages were lost. Their small body sizes (compared to those of some of the giant reptiles and cephalopods, for example) may have allowed crustaceans to persist in a time of great ecosystem disturbance and food limitation. Also, although the extent of the geographic range of an individual species confers resistance to background extinction, a broad distribution for the entire group is one of the most important factors enabling lineages to survive mass extinctions (Jablonski, 1991). Reaping the success of radiations in the warm, reef-studded seas of the Jurassic and Cretaceous, many crustacean groups likely had worldwide distributions that enabled them to survive the end of Mesozoic mass extinction.

The Cenozoic can be divided into the Tertiary (65–1.6 mya, including the Paleocene, Eocene, Oligocene, Miocene, Pliocene) and the Quaternary (1.6 mya–present, including the Pleistocene and Holocene). The Atlantic was now formed and widening. India crashed into Eurasia, creating the Himalayan mountains. Extensive folding, resulting in the Alps, Caucasus, and other mountains, occurred as parts of Africa fused with Eurasia, forming Asia Minor and constricting the ancient Tethys seaway into the isolated, sometimes dry, Mediterranean and Black Sea areas. Mountain building continued in the Rockies, the Coast Range, and the Andes, eventually shifting the flow of the Amazon from westward to eastward. The early Tertiary climate was warm, wet, and mild. The great radiations of placental mammals began. Horses, camels, rhinoceroses, dogs, cats, whales, bats, and primates diversified in Eocene terrestrial environments. A gradual cooling trend began in the Oligocene. Extensive plains, grasslands, and new mammalian lineages (deer, elephants, antelopes, giraffes, and the ancestors of cattle and pigs) developed through the Miocene, and large mammalian carnivores radiated in the Miocene and Pliocene.

In the oceans, there were no extensive coral reefs in the Paleocene, although scleractinian corals had survived the mass extinction at the end of the Mesozoic. The Eocene brought a reradiation of reef-building corals and many families and genera of fish, mollusks, and crustaceans that survive today. Extensive volcanism and tectonic movements in the first half of the Tertiary set the stage for island fringing reefs and the development of atolls in the Pacific.

The Tertiary produced a new radiation of the cirriped barnacles, including the coronuloids (which live as commensals on whales and turtles and appeared in the Paleocene) and the first modern intertidal balanoids (which originated in the Eocene and diversified again in the Miocene). The ostracods radiated once again during the Eocene; they also are represented in the Paleocene and Miocene fossil records. Among the branchiopods, the first definitive anostracans and cladocerans appeared during the Eocene. In the stomatopod hoplocarids, a possible scudid bathysquilloid, the squilloids, and the first pseudosquilloids are known from the Eocene; in addition, fossil gonodactyloids and squilloids are recorded from the Miocene, and squilloids from the Pliocene. Following a late Paleozoic genesis, the isopod peracarid eumalacostracans radiated during the Eocene, and the first amphipod peracarids appeared; both of these groups are known also from the Oligocene and Miocene. Among the eucarid malacostracans,

the caridean shrimps left fossils in the Oligocene and Miocene, and the thalassinidean shrimps are recorded from the Miocene; both groups hailed from the Jurassic. The astacid crayfish and lobsters, among the first of the Paleozoic decapods, are known from the Eocene. The brachyuran crabs, also from a likely Paleozoic heritage, underwent major radiations in both the Eocene and Pliocene, with many of the modern freshwater and terrestrial lineages developing in the latter epoch. Brachyurans are represented in the Paleocene and Miocene fossil record as well. Anomurans are known from the Oligocene and Miocene.

One of the most significant events in the late Tertiary was the gradual establishment of a complete barrier to circumtropical ocean circulation about 3 mya as mountain building along the west coasts of North and South America created a Central American isthmus that linked the two continents. This removed the ameliorating effect of the circumtropical current on the climate and created a much smaller, basin-like West Atlantic region as well as a long thin East Pacific region. Considerable extinction and divergence of new genera and species ensued in the New World tropical seas.

In spite of a minor mass extinction at the end of the Eocene and deteriorating ocean circulation in the Miocene and Pliocene, however, no major groups of crustaceans were lost during the Tertiary. The ostracod and cirriped maxillopods, the stomatopods, the isopod and amphipod peracarids, and the brachyuran decapods all underwent major radiations, particularly during the Eocene.

The Quaternary (Pleistocene 1.6–0.01 mya, Holocene 10,000 years ago-present) ushered in four major periods of glaciation, particularly on the northern continents (North America, Europe, North Asia) that had not been extensively glaciated during the Paleozoic and Mesozoic. Early humans appeared in the Pleistocene. Mountain building in the Cascades, Andes, Caucasus, and the Himalayan regions continued, and rifts in eastern Africa, Asia Minor, Baikal, and south-east Asia reflected continuing tectonic shifts. Worldwide sea levels receded with the advance of continental glaciers and advanced during warmer interglacial intervals. The current climate represents emergence from a colder glaciated interval about 10,000 years ago. The extent to which the frigid polar glaciation impacted climate and seawater temperatures at lower latitudes is debated. Most modern coral reefs (including Australia's Great Barrier Reef) are only about 10,000 to 15,000 years old and represent a thin surface veneer on a complex topography inherited from past reef communities as they adjusted to changing sea levels. The anostracan branchiopods, isopod and amphipod peracarids, and brachyuran crabs are among the relatively few crustacean groups that were preserved as fossils during the Pleistocene. Although morphological and distributional evidence suggests that some of the smaller and thinly skeletonized lineages were present much earlier, many groups are recorded for the first time during the Holocene. These include the nectiopodan remipedes, cephalocarids, mystacocarids, branchiurans, tantulocarids, ascothoracidan and rhizocephalan cirripeds, bathynellacean syncarids, thermosbaenaceans, mictaceans, euphausiaceans, and amphionidaceans. Many other groups have radiated or renewed their diversification during the Holocene. Showing remarkable evolutionary resilience since the beginning of

the Paleozoic, the ostracods are undergoing a fifth major radiation. The cirripeds show considerable current diversity. The stomatopods, peracarids (especially isopods and amphipods), and decapods (dendrobranchiate shrimps, and especially the caridean shrimps, thalassinidean shrimps, anomurans, and brachyurans) all are undergoing major modern diversification. Although no major lineages have been lost during the Quaternary, today the remipedes, cephalocarids, branchiopods, remaining lower malacostracan lineages (phyllocarids, syncarids) and some of the ancient eumalacostracan lineages such as the palinurans and astacids often inhabit peripheral refugia and appear to have their greatest eras behind them.

Ecological Diversity in Crustaceans

The Habitats That Crustaceans Occupy

The major types of environments inhabited by crustaceans can be separated into 16 major, often overlapping, categories. Of all of these, crustaceans are most commonly found in benthic marine habitats, including both level bottom and coarse (rock and reef) habitats (35 groups). Brackish water (coastal deltas and lagoons, brackish marine caves and tidepools, salty inland pools, and brackish groundwater) is the next most common habitat for which 23 groups (59%) of crustaceans are well suited. Seventeen taxa (44%) are pelagic in the upper part of the ocean (<200 m), and 18 (46%) groups are found in the deep sea (200 to >6000 m), either as pelagic or as benthic species on level bottoms or around hydrothermal vents. Fifteen taxa (38%) inhabit permanent bodies of fresh water (ponds, lakes, streams, rivers), including both benthic and pelagic components. Eight groups (21%) contain species that live in intertidal environments (some of these among sand grains), and 8 (21%) inhabit other semiterrestrial or terrestrial conditions (usually moist conditions or decaying vegetation). Some isopods, some amphipods, and a few brachyurans are truly terrestrial, having achieved independence from water for reproduction. Eight taxa (including 5 highly specialized groups) have adopted parasitism (21%), and 7 groups (18%) include commensals that live on or in other organisms. Seven groups or sections of taxa (18%) flourish at high latitudes, 5 (13%) inhabit either marine or freshwater caves (with various degrees of specialization), and 5 (13%) earn a fragile existence in inland ephemeral freshwater and briny pools. Three taxa (8%) can tolerate hypersaline (very salty) conditions, 3 (8%) are known from hot springs, and 3 (8%) live a specialized existence in groundwater. At least 1 group lives interstitially among the meiofauna (organisms smaller than 0.5mm) in subtidal benthic marine sediments. The number of major taxa that occupy each of the various types of habitat may but does not necessarily reflect the number of species in that environment. This analysis, instead, demonstrates the diversity of major adaptations (in morphology, physiology, and behavior) that crustaceans have developed to accommodate particular environmental challenges. These adaptations provide the underlying framework, overlain by other specializations, on which evolution can proceed in the long run.

The same environmental categories can be used to examine ecological diversity among the different crustacean groups. It is likely that those groups that occupy the greatest diversity of

habitats are the ones that will be able to survive massive environmental change, since not all habitats are likely to be equally affected by most forms of environmental disturbance. As shown in the discussion of taxonomic diversity, the maxillopods and the eumalacostracans (particularly the peracarids and eucarids) are the champions in terms of ability to occupy a diversity of different environments. Following a history of evolutionary success that stretches from the earliest Paleozoic to the present, the ostracods inhabit seven different types of environments. The comparatively recent (late Mesozoic) but ubiquitous copepods also occupy seven major types of habitats, including exceedingly specialized parasitic ways of life, and the ancient thoracican barnacles live in five major habitat types. Among the lower malacostracans, the anaspidaceans are surprising in the diversity of seemingly marginal types of environments that they inhabit (five: permanent fresh water, ephemeral freshwater pools, caves, semiterrestrial, groundwater), and the mysidans have radiated into seven major habitats and lifestyles. Even more remarkable, the therosbaenacean peracarids, with only 11 species, inhabit five different types of environment as categorized earlier (benthic marine, inland salt ponds, fresh and salty groundwater, caves, hot springs). The tanaid peracarids and the anomuran eucarids occupy five and six major types of habitats. The caridean shrimps and brachyuran crabs (decapod eucarids) and the isopod and amphipod peracarids, however, inhabit more different types of environment than any other groups of crustaceans (seven, eight, nine, and nine types of habitat, respectively). Although many carideans and some brachyurans live commensally with other organisms, a fully parasitic existence is the only habitat that these eucarids have not exploited as fully as have some isopods and amphipods. Although caridean shrimps have been at least as successful in fresh water and are more diverse in pelagic environments than the brachyurans, they have failed to invade terrestrial habitats as completely as have the brachyurans, amphipods, and isopods. The isopods are the most successful terrestrial crustaceans, and they, along with most other peracarids, flourish in cold, high-latitude environments as well as the deep sea. Amphipods are less specialized for parasitism and terrestrial existence than the isopods. Like the amphipods and isopods, the carideans and brachyurans have radiated into all major marine environments, including the deep sea and its hydrothermal vents. The carideans likely invaded fresh water very early (Mesozoic), whereas the brachyurans undertook major invasions of freshwater and terrestrial habitats in the Late Tertiary and Quaternary.

A number of crustaceans also modify their microenvironment by commandeering empty shells or other structures, engineering tubes or burrows, and camouflaging themselves from pervasive predation in various ways. Anomurans, tanaids, and amphipods all inhabit vacated gastropod shells; anomuran hermit crabs also inhabit tusk shells, hollow twigs and bamboo, calcareous worm and vermetid mollusk tubes, hollow pieces of coral, and even bottle caps. Some anomurans plant anemones that function in camouflage and defense on their gastropod home. Some dromiid brachyuran crabs carry a clam shell on their backs, and lithodid and majid brachyurans culture domes of sponge or decorate their carapace with algae. Tanaid and amphipod peracarids construct pebble tubes, and

amphipods modify algal structures for domiciles or camouflage. One group of amphipods bores into wood, one group of isopods bores burrows in silt and clay, and acrothoracican barnacles bore into coral to make protective lodgings. Coral-dwelling stomatopods chip, scrape, and modify preexisting holes in coral or reef substratum to suit their needs, and most groups of crustaceans are well represented in preformed crevices and bioeroded holes in hard, especially calcareous, substrata (coral, limestone and reef basement, oyster and tube worm reefs). Many of these organisms, such as the thalassinideans, line and modify the preexisting crevice with silt and mucous for a better fit. Some groups of caridean snapping shrimps construct smoothly lined networks of burrows within sponges. Large species, such as stone crabs, coral crabs, spider crabs, spiny lobsters, and some stomatopods inhabit refuge space beneath bioeroded ledges and caverns on reefs. Several groups of stomatopods, astacid crayfishes and lobsters, thalassinidean shrimps, and brachyuran land crabs, fiddler crabs, and ghost crabs all excavate large (in some species very complex) burrows in mud and sand environments. All of these habitat modifications reflect the pervasive intensity of predation by epibenthic and benthic predators such as cephalopods (particularly octopuses), other crustaceans, and especially fishes. By increasing the complexity of the microenvironment, many of these structures increase the potential for commensal associations and heighten the capacity of the environment to support high species diversity.

The Role of Crustaceans in Biological Communities

Examination of the trophic position of crustacean groups indicates that most crustaceans have relatively generalized feeding habits and most are subject to strong predation. Their abundance, moderate size, and generalized carnivory likely exerts top-down control in some communities. Also, as evidenced by almost universal morphological and behavioral adaptations against predation as well as their importance in the diets of many different predators, the availability of crustaceans as prey for other trophic levels probably is essential for the structure, function, and diversity of many aquatic communities. Cladocerans and copepods support higher trophic levels, including fishes, in freshwater habitats. When their ephemeral habitats are located, anostracans and notostracans are heavily consumed by birds. Anaspidacean syncarids are heavily preyed upon by freshwater fishes if the shrimp are dislodged from their refuges. Stomatopods, mysidans, tanaids, cumaceans, isopods, amphipods, dendrobranchiate shrimps, caridean shrimps, anomurans, and brachyurans all are common in both epibenthic and benthic fish stomachs; cumaceans, isopods, and amphipods are particularly important in the deep sea. Dendrobranchiate shrimps and mud-dwelling stomatopods are important in the diets of many large, commercially important fish, and euphausiaceans and pelagic anomurans are a major source of food for whales, squid, tunas, and seabirds.

Most crustaceans are either generalized predators and scavengers (30 taxa or portions of taxa), or detritus and suspension feeders (35 taxa or parts of groups). Many biologists consider the predaceous, scavenging remipedes to exemplify the primitive feeding mode, but detrital suspension feeding, as seen in the phyllopodous cephalocarids, branchiopods, and

some of the primitive phyllocarid malacostracans, obviously can be traced far back in crustacean history as well. Herbivory is not particularly well developed in crustaceans, although many of the phyllopodous groups (cephalocarids, branchiopods, leptostracans) may ingest phytoplankton and plant material along with other detritus. The suspension feeding ascothoracidan, acrothoracidan, and thoracidan barnacles consume phytoplankton; and some ostracods, isopods, amphipods, and brachyurans feed on micro- or macroscopic plants (some of these species also eat detritus or other organisms as well). Euphausiaceans, however, are important grazers of phytoplankton at high latitudes, and copepods may consume more primary productivity than any other organism on earth because of their ubiquity and consumption of phytoplankton in the largest habitat on earth, the open ocean. The mouthparts of crustaceans are relatively easily modified for piercing and tearing flesh, so strict carnivory and ectoparasitic habits, with the potential for considerable impact on host populations, have evolved in a number of groups, including a cladoceran, branchiurans, tantulocaridans, some ascothoracidan barnacles, isopods, and amphipods. Parasitism is most extremely developed in the endoparasitic copepods and rhizocephalan barnacles; many ascothoracidan barnacles and some isopods also live inside and consume the energy or tissues of their hosts. Large body size and armored claws that smash, crush, or shear hard-bodied prey make stomatopods, palinuran and astacid lobsters and crayfish, and anomuran and brachyuran crabs potent predators that, near the top of their benthic food webs, exert important effect on their local communities.

Life History Patterns of Crustaceans

Although most crustacean groups reproduce sexually, a number of groups, particularly in fresh water and high latitude environments, produce offspring without exchanging eggs and sperm. "Parthenogenesis," a form of asexual reproduction where eggs undergo development without fertilization, is found almost exclusively in the Branchiopoda and Maxillopoda. Other forms of asexual reproduction, such as budding of new individuals from a previous individual, do not appear to be present in the Crustacea, although regeneration of missing body parts is common. In the branchiopods, most anostracans reproduce sexually (and produce fertilized resistant eggs that are dormant during unfavorable conditions), but some populations are exclusively parthenogenetic. Parthenogenesis is common in both notostracans and cladocerans. Some notostracan populations are exclusively parthenogenetic, especially at high latitudes. Notostracans also reproduce sexually, producing fertilized resistant eggs that can withstand harsh conditions. Some species of cladocerans produce males and undergo sexual reproduction only during periods of environmental deterioration, such as autumn; males may be dwarfed and short lived. Some species of conchostracans are exclusively parthenogenetic, and other species may include both parthenogenetic and sexual individuals. In the maxillopods, some freshwater ostracods are parthenogenetic, and other species are both parthenogenetic and sexual. Some harpacticoid copepods are parthenogenetic. Some copepods produce resting eggs that are dormant for extended periods. Of the rare deep-sea tantulocarids, only females are

known, though parthenogenesis is not proven. Evidence suggests parthenogenesis in some thoracidan barnacles. Some terrestrial isopods are parthenogenetic.

Reduction of the prominence of males, as evidenced by short-lived, usually dwarfed males that frequently live on or in the female, is seen in the freshwater cladocerans, parasitic ascothoracidan barnacles (dwarf male free living or lives on female), boring acrothoracidan barnacles (lives on female), sessile thoracidan barnacles (lives on hermaphroditic individual or female), parasitic rhizocephalan barnacles (short-lived dwarf male invades extruded female gonad), and parasitic isopods (lives on female). In the deep sea gnathiid isopods, the second maxillipeds are reduced to flaps that cover the mouth of the nonfeeding male. Few males are known (although sexual dimorphism appears in development) in the pelagic deep sea amphionidaceans, and populations of the primitive procaridid shrimps are composed mostly of females; these skewed sex ratios may be the result of differential mortality in males, reduction in the prominence of the male life cycle, or flexible sex determination (as is common in many crustacean groups) rather than a propensity for parthenogenesis.

The reproductive organs of crustaceans are relatively simple, and both testes and ovaries apparently develop readily, with dominance shifted from one to the other depending on hormonal and environmental conditions. The primitive remipedes and cephalocarids are hermaphroditic. Although most sexually reproducing branchiopods are gonochoristic, some species of notostracans are hermaphroditic and likely undergo sex reversal. In the maxillopods, the sex of the sessile cirripeds is notably flexible. Although most of the parasitic ascothoracidan barnacles are gonochoristic, species in one group are simultaneous hermaphrodites and those in another group are protandrous hermaphrodites. In others, the first arrival to a host becomes female, and the next arrival becomes a male. Most of the sessile thoracidan barnacles are simultaneously hermaphroditic or mixed hermaphroditic and separate sexes (dwarf males may reside either on females or hermaphrodites). Most acrothoracidan and rhizocephalan barnacles, however, are gonochoristic. The other center of sex change is found in the malacostracans. In the peracarids, tanaidaceans usually are protogynous hermaphrodites, or the same population may have both gonochoristic and hermaphroditic individuals. Sex change appears to be influenced by environmental factors, possibly even the ratio of males to females as affected by predation. Most isopods are gonochoristic, but some (especially freshwater) lineages change sex. Both protandrous and protogynous species are known, and both gonochoristic and hermaphroditic individuals may occur in the same population. Particularly in parasitic isopods, sex is determined by the presence or absence of another individual; first arrivals become females and the second arrival becomes a dwarf male that resides on the resident female. Most amphipods also are gonochoristic, but protandrous species are known, and some species are composed of both protandrous and gonochoristic individuals. Although most caridean shrimps have permanent separate sexes, some species are simultaneous hermaphrodites and some are protandrous. Both gonochoristic and hermaphroditic individuals may occur within some populations. Sexual differentiation may be affected by both social and environmental factors. For example,

some species of snapping shrimp live in colonies of up to 350 individuals in a sponge, with only one large reproductive female, the “queen.” A host of smaller male or non-reproductive “workers” defend the colony and maintain communal burrows.

Sexual reproduction often is accompanied by morphological structures that have differentiated between males and females, probably as the result of sexual selection. Males often are adapted for greater motility than females. In the ascothoracidan barnacles, the female’s body is enveloped entirely within the carapace, while most of the swimming appendages are exposed in males. Male tanaids have well-developed pleopods, but abdominal appendages are absent in females; males also have larger eyes and more antennal sensory structures than females. Male cumaceans bear abdominal pleopods while females do not, the antennae are reduced in females but not males, and the eyes are more reduced in females than males. The carapaces of female thermosbaenaceans and amphionidaceans are very enlarged, while those of the males are reduced, exposing swimming appendages. The last pair of thoracic legs are absent in female amphionidaceans but not in males, and the females, with reduced mouthparts and a vestigial gut, do not feed.

Various appendages have been modified in many groups to facilitate mating. The first pair of maxillae (maxillules) were modified as a clasper in males of the Devonian Lipostracans (allied to the cephalocarids). The antennae are modified for detecting or holding females in male anostracans; some cladocerans, ostracods, and cumaceans; and in many amphipods. The size and shape of the antennules of male leptostracans and euphausiaceans and of some species of copepods are modified, probably for clasping females. Other secondary sexual characteristics include copulatory structures, which are common in crustaceans. Anostracans have a pair of eversible penes on the first two abdominal segments. The leaflike appendages of the first two trunk segments are modified for copulation in conchostracans; the first two trunk limbs of some genera of ostracods are modified to assist mating, and the third trunk appendages often are modified into copulatory organs. The fourth trunk appendages, sixth thoracopods, and second through fourth thoracopods of male mystacocarids, copepods, and branchiurans, respectively, are modified for copulation. Abdominal appendages have been fused into a single long median penis, the only remaining vestige of the abdomen, in thoracican barnacles. Paired penes also are fused into a single median penis in the tantulocarids and some isopods. A pair of copulatory tubes are associated with the eighth thoracopods in male stomatopods, and the eighth thoracopods are modified, probably for copulation, in the bathynellaceans. The bases of the eighth thoracopods in male thermosbaenaceans bear a pair of well-developed penes. Male mictaceans sport a copulatory process on the eighth abdominal segment, and, although pleopods are otherwise absent in both males and females, male mictaceans retain the second pair of pleopods, probably to assist transfer of sperm. The anterior abdominal pleopods are structurally modified to assist copulation in many male malacostracans, including stomatopods, mysidans, isopods, amphipods, and dendrobranchiate shrimps. The anterior pleopods of both male and female euphausiaceans are elaborately modified for copulation.

Several groups of crustaceans exhibit strong sexual dimorphism in body size and other structures, including the late Paleozoic pygocephalomorph mysidaceans. Sexual dimorphism can be observed among developing juvenile amphionidaceans after stage 9. Male tanaids show pronounced sexual dimorphism in a variety of sensory structures as well as relative size of the chelipeds. The overall morphology of male and female tanaids becomes so highly modified as they molt into copulatory versus noncopulatory phases that they frequently have been misclassified as different taxa. Amphipods and caridean shrimps show similar variability of body size and shape between copulatory and noncopulatory stages, probably reflecting the impact of strong selection for attracting and defending mates against other suitors. Some groups of isopods (especially terrestrial lineages) show extreme dimorphism in size, with males greatly exceeding the size of females. The claws of many decapods (including some caridean shrimps, some anomurans, and particularly some thalassinidean shrimps, astacid crayfish and lobsters, and many groups of brachyuran crabs) are greatly enlarged in males. Either both or only one of the claws may be enlarged for fighting or behavioral displays. Mating or territorial displays often are associated with enlargement of only one claw, as in the fiddler crabs that attempt to attract females to their burrows with colorful choreographic waving displays. Though not sexually dimorphic, stomatopods also seek to attract mates by exposing species-specific colored eyespots and iridescent patterns on their spread maxillipods. Several groups, including land crabs and fiddler crabs, use sound vibrations (usually stridulating or thumping the walls of their burrow) to attract mates. Various other crustaceans stridulate (stomatopods, some isopods, palinurans, other brachyurans), but these sounds may function to deter attacking predators rather than to attract mates. Bioluminescent photophores on euphausiaceans may facilitate sexual identification, although this is not proven. One of the most sensational courtship displays in crustaceans is created by male ostracods that emerge from coral reef substratum about an hour after dark, emitting sequential puffs of bioluminescent material from the maxillary glands in a species-specific pattern as they ascend toward the surface. Different species deposit the discrete puffs of light in uniformly spaced vertical strings, suspend them in a line at a 45° angle from the substratum, or place sequential clusters at different heights. Females do not emit bioluminescent puffs, but emerge from the reef and follow the trail of lights to mate with the displaying males. A horde of nonluminescent males also follow the light trails, apparently to “sneak” matings with the pursuing females.

Most crustaceans produce round nonmotile sperm, although the sperm of some maxillopod groups are flagellated. The sperm, released either in seminal fluid or in packets of spermatophores, are deposited directly into the female genital openings or into a fused medial receptacle. Females may store sperm for long periods (up to several years in some astacid lobsters), although subsequent matings can dilute the sperm of a particular male.

Most crustacean matings are relatively brief (minutes to hours), but some crustaceans undertake long arduous courtships and maintain long-term pair bonds. Since little paternal care or mate provisioning is documented, most pair bonds

probably function to ensure that another male does not also fertilize the female. Males of isopods, amphipods, and brachyuran crabs often sequester females, holding and carrying the smaller female for extended periods prior to copulation, which frequently follows female molting. In the violently aggressive and solitary stomatopods, mating is accompanied by an extended period of courtship (involving both visual displays and tactile stroking) that gradually mediates the tendency to smash the potential mate with the clublike or spearing raptorial appendages. The male and female reside together (either in the female's or male's burrow, depending on the taxonomic group) for a number of days, copulating repeatedly. After as much as a week, the female's aggressive levels rise and she evicts the male before laying the eggs. Commensal pinnotherid crabs ("pea crabs," which inhabit oysters and other organisms' burrows), parasitic isopods, stenopodid shrimps, and many groups of caridean shrimps usually are found in pairs, and probably maintain extended (seasonal or permanent) pair bonds. Some deep-sea stenopodid shrimps apparently colonize glass sponges as postlarvae, and the male and female (perhaps the opposite sex is induced in the later arrival) become permanently imprisoned in the crystalline grid-work of the sponge as they grow. These life-long pair bonds are the source of a romantic oriental legend.

Most crustaceans brood their young, but there is a surprising diversity in methods of treating the young, and some release the embryos free into the environment. The remipedes probably shed their embryos directly into the water (no brooding structures have been observed). In the branchiopods, the notostracans brood their embryos very briefly, then deposit them on the substratum, while most cladocerans release their embryos into the water. In the maxillopods, some ostracods release embryos directly into the water and some deposit them on the substratum. The interstitial mystacocarids apparently lay their embryos free among sand grains. Some copepods release embryos directly into water. Branchiurans leave their host to attach their embryos to a plant or rock. In the malacostracans, the extinct Late Paleozoic belotelsonideans, waterstonellideans, and palaeocaridaceans probably shed their embryos directly into the water, since no structural adaptations for brooding have been seen. Contemporary anaspidacean syncarids, and probably bathynellaceans, release their embryos directly into the environment. Contemporary stomatopods deposit their eggs in a free wheel-shaped disk that the female holds in her maxillipeds, grooming and defending them for several weeks. Most euphausiaceans and most dendrobranchiate shrimps shed their embryos directly into the water.

However, most crustaceans exhibit a variety of structural, physiological, and behavioral modifications to better protect their progeny. Cephalocarids brood one or two embryos at a time on anterior abdominal processes, and the allied Devonian lipostracans had a flap-like egg pouch. Among the branchiopods, the anostracans carry their eggs briefly in an egg sac before releasing them. Some cladocerans shelter their eggs in their carapace; the embryos even obtain nutrients from the sides of the brood chamber in some species. One species of cladoceran broods eggs in the molted carapace. Conchostracans carry their embryos on the thoracopods inside the bivalved carapace. Most ostracods brood their young inside

the bivalved carapace. Copepods usually drag an egg sac behind the body, but some brood embryos on the sixth thoracopods. In the ascothoracidan cirripeds, the female's carapace is enlarged (enclosing her body) for brooding the young. Embryos are released at the nauplius stage or retained in the carapace through all larval stages up to the cyprid. The embryos of acrothoracican cirripeds hatch at an early stage but are brooded in the carapace through the cyprid stage. The body of thoracican barnacles is engulfed by a fleshy mantle cavity in which the embryos are brooded through the nauplius stage. In the malacostracans, leptostracan females brood embryos under their carapace until after two larval molts. As noted earlier, female stomatopods undertake extensive care and protection for their free egg mass within their cavities in coral or excavated burrows in sand or mud. Female mysidans bear a brood pouch on the last two or three thoracopods. The enlarged, thin, blood-filled carapace of female thermosbaenaceans serves as a brood chamber as well as for respiration. Similarly, the carapace of female amphionidaceans is thin and greatly enlarged, and it may be used for brooding. In this group, the first pair of pleopods, greatly enlarged and extending anteriorly beneath the carapace, are thought to assist in brooding the young. The brood pouch is particularly well developed in the tanaids, cumaceans, mictaceans, isopods, and amphipods. This "marsupius" is formed from expanded flaps, called oostegites, at the bases of thoracopods 3 to 6 in tanaids and cumaceans. Sometimes the oostegites are restricted to thoracopod six in tanaids. Cumaceans, like isopods, bear an additional oostegite projecting toward the posterior from the maxillipeds. Female mictaceans bear oostegites either on thoracopods 2 to 6 or 3 to 7. Female isopods have oostegites on the second to fifth, second to sixth, or all eight thoracopods. One family forms a brood pouch from ventral extensions of the body wall rather than oostegite projections from the base of the legs. Several types of internal brooding are present in isopods, including paired invaginated pockets in the cuticle with narrow openings and a single median pocket extending into the thorax between the sixth and seventh segments. Two groups (the gnathiids and flabelliferans) brood young within the body cavity itself; in the flabelliferans, the enlarged oviducts serve as uteri and the oostegites are reduced to small flaps covering the gonopore. Female amphipods develop oostegites on the third to fifth, third to sixth, or fourth to fifth thoracopods; many amphipod taxa also have simple or elaborate gills that protrude from the base of the thoracopods; in some cases the oostegites are reduced and the gills provide a brood chamber. A few euphausiaceans and one species of dendrobranchiate shrimp brood embryos on their posterior thoracopods. Most other decapods, including the carideans, stenopodideans, thalassinideans, astacids, palinurans, anomurans, and brachyurans, brood embryos on their pleopods.

Crustacean embryos proceed through some form of spiral cleavage, often highly modified by the amount of yolk present, to form a nauplius larva, a triangular shaped organism (larger in the anterior) with a simple median eye (ocellus) and three pairs of biramous appendages (the future antennules, antennae, and mandibles). The embryo may either emerge as a plankton-feeding nauplius when yolk reserves are depleted, or the nauplius may be laden with yolk, reducing the need to feed until a later stage. Larvae hatching as nauplii require long

developmental times and are observed in many of the “less advanced” groups (some anostracans, some notostracans, some cladocerans, conchostracans (yolkey), some ostracods, mystacocarids (develop in interstitial sand), nonparasitic copepods (nonfeeding), some ascothoracidan cirripeds, some acrothoracidan cirripeds, some thoracidan cirripeds, rhizocephalan cirripeds (nonfeeding), euphausiaceans, and dendrobranchiate shrimps). Evolution appears to have progressed toward hatching at a more advanced stage, either as a metanauplius (more segments but still only three appendages), a protozoa (where a metanaupliar stage undergoes a metamorphic molt within the egg membrane to a larval stage with sessile compound eyes, maxillules, and maxillae) or a zoea (a more advanced larval form with stalked eyes and three pairs of maxillilipeds; these swimming larvae eventually hatch into a postlarval form resembling an immature adult). The cephalocarids, fossil lipostracans, some anostracans, some notostracans, some cladocerans, some ostracods, some ascothoracidan cirripeds, and some acrothoracidan cirripeds hatch as metanauplii. The reduction or loss of the free larval stage is accomplished by retaining the naupliar, metanaupliar, or protozoal stages within the egg membrane during a longer brooding period before hatching or, in some cases, by shortening the total development time by omitting the morphological development of some or all of these larval stages entirely.

Crustaceans have three types of development, including “direct,” “anamorphic,” and “metamorphic” development; the last two forms sometimes are called less and more extreme types of “mixed” development. In direct development, embryos hatch as juveniles that resemble miniature adults, either because larval stages are passed inside brooded eggs before hatching, because they have been suppressed or lost, or possibly because they never were present. Direct development probably occurs in remipedes and probably was present in the Cambrian canadaspid malacostracans, either because larvae were suppressed or never present. Also, most cladocerans, most ostracods, most branchiurans, leptostracans, anaspidaceans and bathynellaceans, and all of the peracarids show direct development. The young hatch as an adult-like juvenile in some freshwater and terrestrial astacids and brachyurans and in some taxa of very small body size, including some stomatopods and some of the very small caridean shrimps. Most of the instances of abbreviated larval phases probably are explained by passage of larval stages within brooded eggs, but some cladocerans, some ostracods, branchiurans, and the anaspidacean and bathynellacean syncarids do not brood. Either larval stages were suppressed or never were present in these groups.

In anamorphic development, embryos hatch as some form of naupliar, metanaupliar, or later-stage larva, and the adult form is gradually achieved by a progression of morphological changes as the larva acquires more segments and appendages. Anamorphic development is found in many cephalocarids and allied fossil lipostracans, anostracans, notostracans, some cladocerans, conchostracans, some ostracods, mystacocarids, copepods, and one group of branchiurans. In the stomatopods, euphausiaceans and amphionidaceans, the morphology of the larvae generally resembles the form of the adult (thus not requiring a major metamorphosis) so these groups could be considered to have anamorphic development; however,

these three groups usually are considered to have metamorphic development because they have protozoal and zoeal larval forms.

In metamorphic development, the embryo hatches as some form of naupliar, metanaupliar, or later stage larva and develops with a body form that is radically different from that of the adult; thus, a major morphological reorganization (similar to that of holometabolous insects such as caterpillars and butterflies) is required before the adult stage can be attained. All of the eucarids as well as the stomatopods usually are considered to have metamorphic development because they possess protozoal and zoeal larval forms. Other groups that undergo a major metamorphosis between the larval and adult phases include the cirripeds, although they lack the typical protozoal and zoeal stages. The cirripeds are unique in developing a morphologically distinct nonfeeding bivalved postlarval form called a cyprid before transforming into the adult phase. In thoracicans, the cyprid attaches to the substratum with its antennule and reorganizes its body into a sessile adult. In addition to a cyprid stage, boring acrothoracidans metamorphose into a postcyprid pupa stage in order to reorganize itself into the adult form, similar to holometabolous insects. Following four feeding naupliar stages and a nonfeeding cyprid stage that attaches to the prospective host, the parasitic rhizocephalans form a hypodermic-like “kentrogon” stage through which the body, completely transformed, injects itself into the host’s body. The parasitic tantulocarids and copepods also undergo metamorphoses in order to attain the highly modified adult parasitic form. The naupliar larval forms are suppressed in parasitic copepods, which hatch as copepodites (small juveniles).

The number of eggs produced by crustaceans generally correlates with body size, with larger species within lineages usually producing vastly more eggs than smaller species. This tracks only within lineages, however, and, if multiple lineages are combined, there is no trend. Certain crustacean groups are characterized by “weedy” life history characteristics while others are long lived and slow to reproduce. Anostracans and notostracans usually live only a few weeks and produce many eggs, including resistant eggs that are capable of surviving long periods of unfavorable conditions, similar to the seed banks of desert plants. Some copepods also produce dormant eggs. Cladocerans pass through several generations in one summer season. Amphionidaceans may be short-lived as adults (the female does not feed), and males in several taxa (gnathiid isopods, dwarf males in rhizocephalan cirripeds) are short-lived and do not feed. On the other hand, mysidans reproduce infrequently and may require up to 7 years to mature. Some Arctic cumaceans have delayed maturity and live many years, reproducing little. Some stomatopods, astacid and palinuran decapods, and some brachyurans live many years.

The significance of the type of development and number of eggs produced in crustaceans lies in their relationship to dispersal. Species that produce more eggs and those that are released at early stages so that longer periods are spent in the plankton have the largest geographic ranges and are the most resistant to environmental change and extinction. The resistant eggs of anostracans and notostracans often are dispersed by wind or on the feet of birds. Nonparasitic copepods develop through six naupliar stages and five copepodite stages.

Stomatopods pass several protozoal stages (advanced naupliar or metanaupliar stages) in the egg while brooded by the female. The protozoal stage, termed an "antizoea" or "pseudozoea," is followed by four to eight or nine zoeal stages, called "erichthus" or "alima" larvae, in small reef and larger level bottom lineages, respectively. These modified zoeae are pelagic for periods that range from 3 to 4 weeks to 9 months in small reef versus larger level bottom species, respectively. A minority of small species of stomatopods produce only a few, unusually large eggs relative to their body size and undergo their entire larval development within the burrow of the female. Stenopodid shrimps, palinuran lobsters, and some anomurans are characterized by many larval stages and long pelagic phases. Most small species, most species that inhabit fresh water and terrestrial habitats, many species that inhabit high latitude or deep cold environments, and species with anamorphic or metamorphic development that hatch at advanced stages are likely to produce fewer, relatively larger eggs with shorter pelagic phases. These species, and those with direct development, are most likely to have extremely restricted, endemic distributions.

The Geographic Distributions of Crustaceans

Many of the geographic distributions for each of the major groups of crustaceans strongly reflect ancient conditions where the group originated, indicating that dispersal (usually by long lived pelagic larvae) has not dominated the historical ecology of many groups of crustaceans. The importance of intermediate dispersal in speciation, however, where larvae travel far enough to establish new populations but not sufficiently frequently to swamp arising genetic variants, is well illustrated in the thoracican barnacles. Also, the long lived pelagic phases of some of the large level bottom stomatopods have been shown to dampen diversification within and among regions, while those lineages with short lived larvae and significantly more restricted geographic ranges rapidly speciate and also suffer higher rates of apparent extinction (Reaka 1980; Reaka and Manning, 1981, 1987). The distributions of fossil taxa are not extensively considered below because, except for the worldwide distributions of the archaeostracan phyllocarid malacostracans, many extinct taxa are recorded from relatively few regions, possibly as a result of preservation bias.

To understand patterns of distribution in contemporary crustaceans, data for all of the major taxa were divided into nested categories where the entire group (subclass, order, or suborder) had a wide ($>$ half the circumference of the earth) or narrow ($\leq$ half the earth's circumference) global distribution, those with many ($>$ 100) or few species ($\leq$ 100), and those in which most of the individual species had wide or narrow geographic ranges, producing a table of eight columns. This procedure revealed the somewhat surprising result that entire lineages of crustaceans with narrow distributions are rare.

Restricted geographic distributions for entire lineages are found only in four taxa (the nectiopodan remipedes, anaspidean syncarids, thermosbaenacean pancarids/peracarids, and spelaeogriphacean peracarids). Each of these groups also contains few species (10, 15, 11, and 2, respectively) that all have highly restricted individual geographic ranges (one or a few localities). These four lineages likely represent the

remnants of once more broadly distributed groups that have experienced extinction outside of the marginal refugia they currently inhabit. There are no lineages with narrow distributions and few but broadly distributed species, and no lineages with narrow distributions and many species with either wide or narrow species ranges.

Among groups where the entire taxon has a broad distribution, only six groups have low species diversity and contain species with restricted geographic ranges (cephalocarids (10 species); tantulocarids (5 species); bathynellaceans (100 species); mictaceans (3 species); procaridid shrimps (3 species); and stenopodidean shrimps (25 species)). Widely distributed lineages with few species but broad species ranges include another seven groups (notostracans (11 species), mystacocarids (10 species), acrothoracicans (most of the 50 species), leptostracans (most of the 13 species), lophogastridans (most of the 40 species), euphausiaceans (more than half of the 90 species), and the single, though variable, amphionidacean species).

Groups in which the entire taxon is widely distributed on a global scale and that contain many species with broad species ranges are not numerous. Only most dendrobranchiate shrimps and most palinurans fit clearly within this category, although whether the majority of copepods, cumaceans, anomurans, and brachyurans have wide or narrow individual species ranges is not well documented.

By far the most common distribution pattern observed in crustaceans includes lineages that are speciose ($>$ 100 species), broadly distributed on a global scale, and contain species with relatively restricted geographic ranges (14 groups, 18 if copepods, cumaceans, anomurans, and brachyurans, whose status is not certain, are included). These lineages include most of the ostracods ($>$ 8000 species), anostracans ($>$ 180 species), probably most of the cladocerans ($>$ 450 species), most of the conchostracans, ($>$ 180 species), most of the branchiurans (150 species), most of the thoracicans ($>$ 800 species), most of the stomatopods ($>$ 400 species), probably most of the tanaids ($>$ 850 species), most of the isopods ($>$ 4000 species), most of the amphipods ($>$ 6000 species), probably most of the carideans (2500 species), and probably most of the thalassinideans and astacideans.

In summary, the major lineages of crustaceans are most commonly broadly distributed on a global scale (29 of the 33 taxa documented). However, the dominant pattern for species is to have relatively restricted geographic ranges. In at least 24 of the 33 groups documented, the majority of species have relatively small geographic ranges, in some cases restricted to a single locality. Lineages containing many species and those with few species are about equally represented (16 and 17, respectively).

Vulnerability to Extinction

Extinction in the Fossil Record

Extinction in the fossil record tells us a considerable amount about how prone modern crustaceans are to extinction. Studies show that the breadth of geographic distribution of a species or lineage, which is intimately intertwined with their larval dispersal potential, is the single most important

predictor of extinction. Factors that favor extinction or survival, however, depend on whether one is considering organisms during normal levels of background extinction or during cataclysmic mass extinctions (Jablonski, 1991). During background conditions, lineages with long-lived planktonic larvae persist longer in the fossil record (i.e., have lower extinction rates) than those with abbreviated development, individual species with broad geographic ranges suffer lower extinction than those with narrow endemic distributions, and lineages characterized by high species richness survive longer than those with few species. Species-rich lineages composed of broadly distributed species have especially high survival. During mass extinction episodes, however, all of these traits are ineffectual, and the broad geographic deployment of an entire lineage, regardless of the ranges of the individual species or the number of component species, is the primary characteristic that increases the likelihood that the lineage will persist into the next geological era (Jablonski, 1986, 1991).

Jablonski (1991) designated nine major mass extinctions (Late Ordovician, 61% and 85% of genera and species lost; Late Devonian, 55% and 82% of genera and species lost; Late Permian, 84% and 96% of genera and species lost; Late Triassic, 47% and 76% of genera and species lost; Middle Jurassic, 26% and 53% of genera and species lost; End Jurassic, 21% and 45% of genera and species lost; Middle Cretaceous 26% and 53% of genera and species lost; End Cretaceous 47% and 76% of genera and species lost; Late Eocene, 15% and 35% of genera and species lost). Of 15 crustacean lineages that became extinct, 9 of them did not persist beyond one of these biotic crises. Although this does not prove that the mass extinctions were directly responsible for their demise, the failure of lineages to survive into the next period, especially in taxa that had persisted through several previous geological periods, suggests that the conditions associated with the mass extinction may have contributed to their disappearance. In many cases, representation in the fossil record is too spotty to determine whether the lineage and its component species had broad geographic ranges, but some useful information can be gleaned from what we know about fossil crustaceans. The lipostracans (allied to the cephalocarids) and the archaeostomatopod hoplocarids are known only from the Devonian, and the kazacharthrans (allied to the notostracans) are recorded only from the Jurassic. Mass extinctions closed both of these periods, and it appears that these lineages were not widely distributed, being known only from Laurentia (North America and Europe), Scotland, and Kazakhstan, respectively. Also, only a few species are known in each lineage. Known only from equatorial Laurentia in the Cambrian and Ordovician, the hymenostrocan phyllocarid malacostracans did not survive beyond the Late Ordovician mass extinction. The extraordinarily successful archaeostracan phyllocarid malacostracans persisted from the beginning until the end of the Paleozoic, making it through both the Late Ordovician and Late Devonian crises but failing to survive the greatest of mass extinctions in the Late Permian. This lineage had a worldwide distribution and included many taxa that occupied diverse habitats; these factors may have facilitated their persistence through several major crises but were not sufficient to allow survival through the End of Paleozoic debacle. Other primitive malacostracans, including the waterstonelliids,

eocaridaceans, paleocaridacean syncarids, and pygocephalomorph mysidaceans, arose in the Carboniferous but also perished during the End of Paleozoic extinction. On the other hand, however, one order of the primitive remipedes (the enantiopodans), the canadaspid and hoplostracan phyllocarid malacostracans, the aeschronectid hoplocarids, and the belotelsonid malacostracans, all known only from the Carboniferous, and the palaeostomatopod hoplocarids, which originated in the Devonian and persisted until the Carboniferous, all perished in the absence of a major biotic crisis.

Tropical, especially reef, biotas have throughout history suffered disproportionately greater losses to mass extinctions than those at higher latitudes (Jablonski, 1991). Perusal of the habitats and distributions of the extinct fossil crustaceans suggests that most of those lost occurred in regions that were tropical at the time. The tropics also are the largest source of evolutionary novelties (due to speciation and development of major new adaptive types). This is possibly because the recurring extinction events open new evolutionary opportunities there, because high diversity in the tropics makes origination of new types more probabilistic simply because of the large numbers of lineages available for genetic experiments, or because something about the ecology of tropical environments causes greater divergence per speciation event (Jablonski, 1993).

Low density and small total population size also has been shown to render species susceptible to extinction in some taxa (Raup, 1986), and this characteristic has been of overriding concern to many conservation biologists in recent years. Evidence on the importance of population density as a predictor of extinction is equivocal in crustaceans. On one hand, the archaeostracan phyllocarid malacostracans were one of the most abundant benthic organisms, and they persisted from the Cambrian until the end of the Paleozoic, supporting the thesis that population density is important. On the other hand, however, the archaeostomatopod hoplocarids were abundant during the Devonian but did not survive into the next period. Aeschronectid hoplocarids dominated their benthic communities and belotelsonid malacostracans were abundant during the Carboniferous, but neither persisted beyond that period. Waterstonelliid malacostracans formed abundant aggregations, palaeocaridacean syncarids were very numerous, and pygocephalomorph mysidaceans were among the most important components of their communities during the Late Paleozoic (Carboniferous to Permian); yet all succumbed to extinction at the end of the Permian.

Similarly, when a species occupies a unique or particularly restricted type of habitat, environmental changes are more likely to entirely eliminate these localized populations, and individuals may be unable to find or migrate to a similar specialized environment. This feature of organism-environmental interaction also has been a dominant concern in conservation biology. The evidence from fossil crustaceans on this topic, however, is not clear. An example of a lineage with a very specialized habitat that became extinct is the lipostracans, allied to the cephalocarids, that lived in Devonian hot springs. However, other crustaceans that became extinct were not obviously specialized for unique habitat types and inhabited apparently generalized benthic coastal environments. Enantiopodan remipedes; canadaspid and hoplostracan phyllocarid malacostracans; belotelsonid

and eocaridacean malacostracans; archaeostomatopod, aeschronectid, and palaeostomatopod hoplocarids; palaeocaridacean syncarids; and pygocephalomorph mysidaceans all inhabited shallow benthic coastal environments. Of these, at least the abundant aeschronectids, pygocephalomorphs, and palaeocaridaceans also co-occurred in brackish swamps and deltas, and at least the palaeocaridaceans extended into fresh water. The latter four lineages possibly could be considered to exhibit some habitat specialization (fresh water), but most of the lineages lost to extinction were not habitat specialists.

Broadly compared across phyla, the fossil record shows that species high on the food pyramid (predators or parasites) have sometimes been at risk during environmental perturbations, particularly if they also had achieved large body size and had developed specialized morphology and high levels of activity (e.g., for predation). It is thought that their high metabolic requirements and need for large amounts of food imperils their survival during difficult periods compared to smaller species that usually are lower in the food web. A related concept, known from the 1800s as Cope's Rule, posits that most lineages originate as small generalized forms, evolve toward larger and more specialized morphologies, then become extinct (Stanley, 1973). Body sizes of extinct crustaceans are not synthesized in the literature in most cases, but the few available cast doubt on whether or not crustacean lineages of large body size are particularly susceptible to extinction. Enantiopodan remipedes probably were relatively small, kazaharthrans were small to moderately sized (< 30 mm), and palaeocaridaceans and phygocephalomorphs probably were small to moderately sized for crustaceans. Yet all became extinct. In many crustaceans (Reaka and Manning, 1981, 1987; Reaka, 1980) and among invertebrates in general (Menge 1975; Strathmann and Strathmann, 1982), larger species produce many more small offspring that spend considerably longer periods in the plankton and have wider geographic ranges than smaller species. Larval dispersal and wide geographic ranges tend to slow down both extinction and speciation (Jablonski 1986; Jablonski and Lutz, 1983), suggesting that, in marine invertebrates, dispersal at large body sizes usually overpowers susceptibility to extinction. However, not all large-sized species produce large numbers of widely dispersing offspring (especially in brackish, freshwater, and terrestrial environments or in lineages where abbreviated development is inherited from past legacies), and available food may be sufficiently restricted to prevent reproduction (thus dispersal) during particularly stressful environmental conditions. Thus, although Cope's Rule may apply more universally among fossil vertebrates (which were Cope's original source of data for the pattern of greater extinction in species of large body size) than among invertebrates, large body size still may render lineages susceptible to extinction among invertebrates in some situations.

The Prospects of Extinction in Modern Crustaceans: Which Taxa are Most Vulnerable, and which Ones Represent the Most Urgent Conservation Targets?

Table 2 summarizes the major factors that are likely to affect the viability of contemporary crustacean groups during natural or human-induced environmental changes. Many scientists caution that drastic environmental shifts could occur as

human populations increase exponentially (perhaps doubling in the next 100 years) and affect the atmosphere, soil, and coastal waters (Wilson, 1989). If such change impacts the biotic world in a manner similar to the mass extinctions of the past, the primary factor that would facilitate survival of the crustacean groups analyzed in this study would be wide distribution of entire groups. Fortunately, most (35 of 39) groups of crustaceans are distributed nearly worldwide, suggesting that at least some of these groups probably would survive. The remipedes, anaspidaceans, thermosbaenaceans, and spelaegriphaceans, however, would be at high risk.

If the deteriorating environment resembled background conditions rather than a mass extinction event, however, the number of lineages within the group, the size of the geographic ranges of species, whether or not most of the group inhabited tropical (especially reef) environments, and possibly whether the species were characterized by low population densities, occupied specialized or highly restricted types of habitat, were positioned high in the food web of their communities, or were large and active could influence the probability that they would succumb to extinction over the long run.

Of the 34 groups for which data were available on species numbers, 25 groups (74%) were considered to be at risk as a result of relatively few species within the lineage (14 at high risk, 11 at moderate risk). The remipedes, cephalocarids, notostracans, mystacocarids, leptostracans, tantulocarids, anaspidaceans, thermosbaenaceans, and spelaegriphaceans all have fewer than 15 species and would be at very high risk. Even more notable, the mictacean and procaridid lineages are represented by only 3 species each, and only 1 species is known in the entire Order Amphionidacea. These phylogenetically unique groups could easily be lost.

Of 39 groups, 27 (70%) are composed of species with mostly restricted geographic ranges. Ten of these groups contain species with especially restricted distributions, considered at high risk, and 17 contain some species with restricted ranges that are judged to be at moderate risk. Of the 39 groups, 14 (36%) are considered to be at risk because they are primarily tropical or reef dwelling. Twenty-seven (74%) of the 39 groups are characterized by small population sizes. Eight of these have especially low densities or total populations and are considered to be at high risk, and 19 appear to be at moderate risk. Of the 39 groups, 29 (74%) occupy unique or highly specialized types of habitats; 11 and 18 of these are judged to be at high or moderate risk, respectively, because of their degree of habitat specialization. Although many crustaceans are predators or parasites, relatively few are at the apex of the food web (this position often being usurped by fishes), and relatively few are species specific in their choice of prey or hosts. Of the 39 groups, 23 (59%) are judged to be at moderate risk due to a relatively high position in the food chain. Also, relatively few entire groups of crustaceans are sufficiently large in body size that their persistence is likely to be imperiled. Large body size is unlikely to be associated with extensive extinction for the following reasons. Wherever the distributions of body sizes among species of a group have been compared, there always are far more species of small than large body size (May 1988; Reaka-Kudla, 1991, 1997), and this almost certainly is true throughout the Crustacea. Also, in many crustacean groups, species of large body size

Table 2 Summary of extinction vulnerability and conservation value of different groups of contemporary crustaceans

<i>Taxon</i>	<i>Few living species (+ + < 100, + < 500)</i>	<i>Entire group restricted geographic range (< half circumference Earth)</i>	<i>Most species restricted geographic range</i>	<i>Group primarily tropical</i>	<i>Small population size</i>	<i>Unique or restricted habitat type</i>	<i>High trophic level</i>	<i>Large body size (or long lived)</i>	<i>Old (+ probably since mid-Paleozoic, + + probably since beginning Paleozoic) or phylogenetically unique lineage</i>	<i>Total score (sum of +, ± counted as 0.5)</i>

produce long-lived pelagic larvae that confer protection against background extinction. The present analysis suggests that 12 of 39 groups (31%) are at possible risk due to their relatively large body sizes (if other life history characteristics do not outweigh the effect of body size).

One of the factors that should be included in prioritizing conservation efforts is the uniqueness of the lineage. Some crustacean groups represent a heritage that stems from half a billion years ago (the beginning of the Paleozoic). Among groups still alive today, the remipedes, ostracods, ascothoracidan barnacles, and thoracican barnacles are known from Cambrian fossils or their morphology suggests that they are derived from the most primitive lineages of crustaceans. Sixteen other groups are known from the Mid-Paleozoic (300–400 million years ago). These ancient groups are more likely than more recently derived groups to have totally novel characteristics, even in their biochemical and genetic constitution. As we enter a millenium in which biotechnology has only begun to offer human benefits through genetic manipulations, we can ill afford to lose these lineages. Some of these ancient groups are particularly vulnerable due to few constituent species, restricted geographic ranges, small populations, specialized habitat requirements, or other factors (especially the remipedes, cephalocarids, notostracans, ascothoracidan and acrothoracican barnacles, leptostracans, anaspidaceans, thermosbaenaceans, spelaeogriphaceans, mictaceans, procaridids, and especially the amphionidaceans). These groups merit special conservation attention.

Table 2 provides a tentative overall summation score for risk factors and intrinsic conservation value in each group. The overall mean risk/value score for the 39 groups was 5.9. Incorporating all of the different risk and value factors, eight groups (the remipedes, tantulocarids, anaspidaceans, spelaeogriphaceans, mictaceans, procaridids, stenopodideans, and thalassinideans) merit the closest conservation scrutiny overall (score of 9 or above). Of these, the remipedes are considered to be the highest priority. This represents only a beginning, however, at assessing which lineages are in most need of protection in order to ensure their survival in the next centuries. Identifying which lineages and where they are most at risk (as well as the most effective methods for conserving them) will be one of the most important tasks for at least the next decade.

Glossary

Centinelan extinction Disappearance of species before their formal recognition by science.

Hyperparasitoid A parasitoid of a parasitoid (e.g., a parasitoid wasp larva living in a parasitoid fly larva that feeds on a beetle).

Parasitoid An organism that spends a significant portion of its life history attached to or within a single host

organism; unlike a true parasite, it ultimately sterilizes or kills the host.

Taxonomic impediment Insufficient amount of taxonomic expertise and tools to identify and describe the world's biodiversity.

Troglobitic Cave-dwelling organisms, adapted to life in complete darkness.

Overview of Terrestrial Invertebrates

Diversity and Species Numbers

To talk about terrestrial invertebrates is to talk about the majority of life. Although the numbers of species of living organisms can only be estimated to the nearest orders of magnitude, recent calculations based on the rate of description of higher taxonomic categories predict the existence of 8.7 million currently living species (± 1.3 million.) Of these, approximately 7.7 million are terrestrial animals, of which only approximately 35,000 are vertebrates (Mora *et al.*, 2011). Thus, by even the most conservative estimates, terrestrial invertebrates constitute at least 80% of all living species, distributed in all inhabitable terrestrial environments. Consequently, the endangerment of any terrestrial habitat is often equivalent to the endangerment of many of its invertebrate inhabitants, the great majority of which remain unknown to science. The relatively small proportion of terrestrial invertebrates that have been formally named (fewer than 2 million species) is in most cases not studied sufficiently enough to make species-level assessment of their endangerment or even provide estimates of their population sizes and distribution. (Note: The term “endangered” is used here to indicate any potential threat to the long-term survival of a species, and not as a category within the International Union for Conservation of Nature (IUCN) Red List ranking system; thus, for the purpose of this article, species listed as near threatened, vulnerable, endangered, etc., by IUCN are considered to be endangered.)

The overwhelming majority of terrestrial invertebrates are insects (including springtails and relatives), and between 1.4 and 1.8 million species of insects have been named. Other groups of terrestrial invertebrates include arachnids (spiders, mites, and relatives) with approximately 100,000 named species; myriapods (centipedes and millipedes) with about 13,000 named species; crustaceans, with fewer than 5000 terrestrial species; velvet worms, with about 200 species; tardigrades, with about 1200; annelids (earthworms), with about

6000 species; land planarians (Geoplanidae), with fewer than 1000 known species; soil nematodes, with at least 15,000 species; and land mollusks (snails and slugs), with approximately 25,000 species.

Taxonomic Impediment

One of the most serious obstacles in effective invertebrate conservation is the existence of the taxonomic impediment, understood as the lack of taxonomic expertise to identify and describe their diversity. Without the ability to recognize species, it is virtually impossible to implement effective measures for their targeted, species- or population-level protection. The taxonomic impediment encompasses not only the shortage of biologists capable of identifying invertebrate animals and recognizing those in need of protection but also the nearly complete lack of tools, such as field guides or keys for identification that could be used by conservation practitioners, such as managers of nature reserves or technical personnel in national parks to identify and monitor population of endangered invertebrates. The impediment is particularly severe in areas with the highest level of invertebrate biodiversity, such as exceptionally species-rich tropical areas of South America and Africa, as well as taxa with presumably little economic importance (e.g., earwigs and centipedes), or those that because of their small size require specialized equipment to identify (e.g., soil mites and nematodes). The only terrestrial invertebrate groups where taxonomic impediment has been largely ameliorated are a handful of groups of particularly attractive butterflies and large beetles, which have a long history of being collected and studied by both entomologists and amateurs. Recently, similar efforts have been underway to develop tools for quick and reliable identification of dragonflies and damselflies, and a few additional groups of terrestrial invertebrates, albeit those efforts concentrate primarily on faunas of the more developed, but less biodiverse countries.

The invention and development of Internet-based technologies within the last two decades have made publishing

and distribution of taxonomic identification tools easier and less expensive, but efforts are still hampered by the insufficient numbers of taxonomists capable of their development. Several international initiatives, such as Global Biodiversity Information Facility (GBIF) or Encyclopedia of Life (EOL), have been involved in the efforts to accelerate digital distribution of tools to reduce the taxonomic impediment. The development of rapid and inexpensive genetic sequencing technologies has led lately to a more widespread use of genetic barcodes, small fragments of (usually mitochondrial) deoxyribonucleic acid (DNA) to identify species. Large, comprehensive databases of genetic barcodes and automated, widely available sequencing will likely soon lessen the taxonomic impediment in invertebrate conservation.

There is evidence that areas too small to support endemic species of vertebrates (e.g., the Antioch Dunes of California) have rich faunas of endemic invertebrates, which are at risk of extinction due to relatively small alteration of those habitats. The current general paucity of expertise in invertebrate taxonomy and identification as well as insufficient efforts to sample and document terrestrial invertebrates in threatened habitats may lead to the negative phenomenon known as Centinela extinction, understood as the extinction of species before their very existence is recognized and documented. While, by the very definition of the process, it is difficult to prove Centinela extinction, the existing knowledge of distribution ranges and dispersal abilities of many invertebrate taxa support the notion that the disappearance or anthropogenic alteration of natural habitats will lead to extirpation of species restricted to those habitats; in the case of Antioch Dunes the extinction of endemic invertebrates, such as the Shield katydid (*Neduba extincta*) following the habitat alteration, has already been demonstrated.

Life Histories

A compounding factor in efforts to monitor and protect terrestrial invertebrates is the presence of polymorphism and complex life cycles in many of their species, where immature forms may have very different appearance and habitat requirements than the adult forms. For example, insects that undergo complete metamorphosis as a rule have very different microhabitat and food requirements than the adults, such as caterpillars of butterflies that often require very specific food plants, different from those that adults use to obtain their nutrients (Van Swaay *et al.*, 2010). Many invertebrates that are terrestrial as adults spend their entire larval development in the water (e.g., dragonflies, mayflies, or some midges). An extreme example of the disjunction between the adult and larval lifestyle is the coconut crab (*Birgus latro*), the largest living terrestrial invertebrate, whose early developmental stages include oceanic, pelagic larvae. This means that any attempts in species- or habitat-level conservation of such organisms must take into consideration all requirements and environments needed by them.

None of the terrestrial invertebrates lives in isolation from other members of its biological communities, and many form obligatory, symbiotic relationships with other species. A good example of such association is that between blue butterflies

(Lycaenidae) and ants. European Scarce Large Blue (*Phengaris teleius*) is a species whose caterpillars need to be picked up by worker ants of the genus *Myrmica* and carried off to the ants' nest, where they feed on ant grubs and eventually pupate. In addition, young caterpillars of this species need to feed on the shrub *Sanguisorba officinalis* for the first 2 or 3 weeks of their life. Because of such complex life history, this butterfly is vulnerable to any changes in the environment that affect either the host plants or host ants, and in large parts of its range, this species declines because of either intensification (e.g., drainage, fertilization, and use of pesticides) or abandonment (where its habitat gets invaded by scrubs and later forest) of its wet meadow habitat. Larvae of the moth genus *Ceratophaga* can only survive in the keratin, such as that of horns of antelopes or shells of tortoises, and thus are dependent on the existence and availability of their vertebrate hosts.

A special case of complex, symbiotic life histories in terrestrial invertebrates is parasitic relationships between insects and their hosts. This includes not only such well-known (and negatively perceived) cases as lice and fleas on vertebrate hosts but also parasitoids and hyperparasitoids that develop in other insects. Braconid wasps, ichneumonid wasps, or meloid beetles all require other insect species to complete their life cycles, and the decline or loss of the host species invariably leads to decline or loss of the parasitic ones.

Threats to Terrestrial Invertebrates

Habitat Loss and Fragmentation

The principal threat to the survival of terrestrial invertebrate species is the loss of their natural habitats. There is evidence that the average distribution range sizes of invertebrate taxa are smaller than the average range sizes of vertebrates, and their dispersal abilities are also lower than those of vertebrates. In addition, species associated with small, isolated or island-like habitats (e.g., peatlands of Europe, subalpine ecosystems, and small oceanic islands) appear to have even lower dispersal abilities, and consequently are more prone to be affected by changes to those habitats, and pushed below the minimal viable size of their population (Bönsel and Sonneck, 2011; Kisdí, 2002). The highly developed parts of the world, such as Europe or the coastal regions of the USA, have already lost the majority of their natural habitats due to centuries of agricultural practices and urbanization, and those habitat that are still relatively intact are usually highly fragmented. Fragmentation is considered a major factor that impacts the survival ability of many terrestrial invertebrate species that require a certain, critical minimum area of continuous habitat or habitat-dependent resources to survive. For example, the American burying beetle (*Nicrophorus americanus*) has disappeared from over 90% of its former range within the past 150 years as a result of anthropogenic habitat loss and fragmentation of relatively continuous stands of deciduous forests across the presettlement range of this species; these fragmented habitats are now currently too small to sustain the fauna of small mammals, on carcasses of which the beetles feed, extensively enough to support its survival. Flightless

species are particularly vulnerable to the effect of fragmentation: brachypterous grasshopper *Prionotropis hystrix rhodanica*, endemic to the Crau Plain area of southern France, is declining rapidly due to increasing fragmentation of the habitat that supports "coussou" type of vegetation, following the intensification of industrial development in the area (Blight *et al.*, 2011). In Japan, the traditional "Satoyama" ecosystem, consisting mostly of secondary woodlands and grasslands, supports a high proportion of the country's endangered species of butterflies. Within the past 40 years, most of the "Satoyama" habitats have been industrialized, causing an over 80% decline in the populations of these insects (Nakamura, 2011).

It is not known what precise effect on local terrestrial invertebrate faunas has been caused by the extensive deforestation and loss of natural habitats in many tropical areas of the world, but it can be safely assumed that it has already contributed to the extinction of many thousands, if not millions of species. For example, Madagascar, an island reputed for its exceptionally high levels of endemism, which in some cases may encompass 100% of species in a given higher taxon, has lost over 90% of its original forest coverage within the past 150 years. This has undoubtedly caused Centinelan extinction on an unimaginable scale, and the remainder of the Malagasy invertebrate fauna is under continuous threat from further losses of natural habitats. The negative effect of deforestation in areas with lower levels of invertebrate endemism, such as the extensive Amazon and Congo Basins, is probably proportionately lower, but the increasing shrinkage and fragmentation of individual forest habitats are likely to accelerate the loss of even relatively widespread terrestrial invertebrate species.

The effect of anthropogenic change is felt particularly strongly by insular faunas of invertebrates: the majority of threatened terrestrial mollusks in Europe occur on the Macronesian Islands (the Canary Islands, the Azores, and Madeira), where a massive pressure due to the increasing urbanization of these islands and the ongoing expansion of the tourist infrastructure exists; it has been shown that even small-scaled disturbances, such as a single road, can destroy the habitat of narrow-range endemic snails, with little chance of recovery from neighboring areas. The orthopteroid fauna (grasshoppers and relatives) of the Seychelles, because of its isolation and inability to be replenished by immigration from other areas, has suffered greatly from habitat disturbance caused by human activity and is now restricted to ever shrinking patches of native vegetation; some species have not been seen for the past 100 years and should be presumed extinct. The effect of roads, especially wide, paved roads, has been demonstrated to increase fragmentation of habitats and depress biodiversity even among relatively vagile invertebrates like beetles (Dunn and Danoff-Burg, 2007).

Cave habitats exhibit many characteristics shared with oceanic islands in terms of their isolation and levels of endemism. Some troglobitic species are dependent for their survival on the availability of external resources, for example, the Table Mountain cave cricket (*Speleiacris tabulae*), depends on bat guano and hence on survival of the bat population. Cave habitats, because of their isolation and relatively static nature, are more sensitive to low-level disturbance than

surface habitats, and even seemingly small anthropogenic impact, such as the increase in the compactness of the soil on the cave floor caused by human visitors, may have negative impact on the troglobitic fauna.

Climate Change

As ectotherms, animals that cannot easily regulate their body temperature, invertebrates are predicted to be affected more severely from climate change than warm-blooded animals. Global climate change will favor generalist, highly mobile species, and there is already ample evidence of species of butterflies and mosquitoes from lower latitudes moving toward higher latitudes and thus into areas where mean annual temperatures used to be too low for their survival. At the same time, cold, island-like habitats near mountain peaks that often shelter endemic invertebrate taxa are shrinking, and populations of cold-loving species that live there are showing signs of decline. The glacial and alpine habitats of the Sierra Nevada mountain range in the western USA have been steadily contracting or entirely disappearing, and several species of endemic ice crawlers (*Grylloblatta*) are presumed extinct due to the loss of these microhabitats.

The general unpredictability of the change in both faunistic and floristic composition of specific habitats that is likely to accompany the global climate change makes planning strategies for invertebrate conservation very difficult. Single site reserve selection or even designation of large protected areas may not be effective in counterbalancing the synergistic effects of the climate change on habitat fragmentation and other anthropogenic disturbance. It is certain that long-term maintenance of the status quo of species composition within any discrete geographic area is unattainable, and future invertebrate faunas will be different, and certainly less species-rich and more homogenous on larger spatial scales.

Pest Control

Invertebrate conservation and pest management are often viewed as directly antagonistic. Invertebrates, and such groups of insects as grasshoppers in particular, are perceived as something to be controlled and curbed, perhaps entirely exterminated. This is despite the fact that less than 10% of all grasshopper species have the potential to become "pests", and some "pest" species have been demonstrated to be highly beneficial to agricultural practices and increase the productivity of pastures (Samways and Lockwood, 1998). Yet the general perception of invertebrates as pests or disease vectors makes it easy to enact control measures against them but often exceedingly difficult to introduce measures toward their conservation.

Over 5 million tons of chemical pesticide are used annually worldwide to control the actual or perceived threat of pest invertebrates. Highly toxic, broad-spectrum insecticides and acaricides (poisons targeting mites) may have a particularly detrimental effect on invertebrate populations, as they do not discriminate between the target and nontarget species, and collateral damage of hundreds, perhaps thousands of species of nontarget invertebrates may result from such control

measures. But although these treatments have immediate and lethal effect on local invertebrate populations, they do not appear to have caused widespread extinction of species. However, they may have negative effects on populations of threatened invertebrate species in habitats adjacent to agricultural areas, and sudden increase in their mortality due to the synergistic effect of the pesticides and habitat fragmentation/alteration may cause them to drop below sustainable population levels. One well-documented case of extinction due to a combination of intense eradication efforts and the overall anthropogenic landscape changes is that of the Rocky Mountain grasshopper (*Melanoplus spretus*), which was considered one of the most important pests in North America in the nineteenth century but became extinct by the early 1900s. A similar case may be unfolding in the Mediterranean region of Europe, where the Moroccan locust (*Docostaurus maroccanus*), once one of the most dangerous agricultural pests, is becoming rare following the conversion of grasslands into croplands and effective pest-control methods. Cases like this raise the question of whether pest species should be protected before they become extinct or allowed to disappear completely.

Introduction of genetically modified (GM) organisms into agricultural practices, particularly plants containing transgenes (genes transferred from other organisms) has caused concern among conservation biologists about their impact on populations of other organisms. The most contentious case was initially that of B.t. (*Bacillus thuringiensis*) gene transferred into corn, which enabled the corn to produce its own pesticides against insects such as the European corn borer. There is evidence that exposure of Monarch butterfly (*Danaus plexippus*) caterpillars to pollen from GM corn increases their mortality, but the overall effect on the population of this species of B.t. corn appears to be relatively low. The use of GM plants may in fact lead to a decrease in the use of broad-spectrum insecticides and have a long-term positive effect on the populations of nonpest species of invertebrates (although the introduction of the "Roundup Ready" GM variety of corn has caused an increase in the use of herbicides, and consequently a decline in insect populations associated with plants perceived as "weeds", including the Monarch butterflies associated with milkweed).

Invasive Species

The threat from alien invasive species is widely perceived to be one of the major causes of species decline and local extinction rates among animals, including terrestrial invertebrates. In South Africa, invasive alien trees have caused exclusion of sun-loving dragonflies from some areas due to the increase in the amount of shade in the habitat, and a similar effect has been noted on the local diversity of acridid grasshoppers. But the overall impact of invasive alien plants on local terrestrial invertebrate communities is poorly known, and in some cases may even lead to an increase in the alpha diversity of insects. A far greater risk is associated with invasion by alien animals, both vertebrate and invertebrate. Introduction of turkeys, hens, and rabbits to Iberian Mediterranean Islands has had a major negative effect on the numbers of tenebrionid beetles,

whereas in Hawaii, the introduction of nonnative poecilid fish has severely impacted populations of endemic *Megalagrion* damselflies. Invasive rats, pigs, and possums in New Zealand have caused local extinctions of several species of land snails, including kauri snail *Paryphanta* spp. and the giant *Powelliphanta* spp. Rats and introduced alien hedgehogs have caused massive decline and local extinctions of giant, cricket-like wetas (*Deinacrida* spp. and related genera) (Watts *et al.*, 2008), and it is presumed that rats, feral pigs, and other alien mammals have led to the disappearance of an unknown number of land invertebrates within the past 200 years in New Zealand.

Invasive insects, and ants in particular, are a major cause of decline or extinction of land invertebrates (New, 2010). The crazy ant (*Anoplolepis gracilipes*) is one of the worst offenders, and this species has been documented to cause exclusion of local ant species in the Solomon Islands, a population crash in the terrestrial red crab (*Gecarcoidea natalis*) on Christmas Island, and local extirpation of native ants (*Odontomachus simillimus*) and ghost crabs (*Ocypode* spp.) in the Seychelles. The Argentine ant (*Linepithema humile*) has displaced native ant species in an ecologically sensitive area in Spain and has been associated with local extinctions of native ants in California, whereas the African big-headed ant (*Pheidole megacephala*) is known to have had a major adverse effect on both local insect and spider populations in those parts of the world where it was inadvertently introduced.

Displacement of native species has also been caused by other groups of insects: the number of alien species of ladybugs (Coccinellidae) in the USA and Canada has increased steadily over the last century while the average proportion of native individuals has remained fairly constant until 1987, followed by a rapid decrease in the past 25 years; consequently, formerly common native species, *Adalia bipunctata* and *Coccinella novemnotata* have become rare in their former ranges.

Other invasive invertebrates include New Zealand predaceous land planarian (*Arthurdendyus veigrandis*), which has been shown to cause strong decline among native earthworms in the British Isles. The European hammock spider (*Linyphia triangularis*) has been introduced to NE, USA, and its large size, competitive ability, and aggressive nature has caused native linyphiid spiders to become scarce or virtually absent in areas it invades. The millipede *Scolopendra morsitans* is believed to be at least partly responsible for the decline of the endemic St. Helena giant earwig (*Labidura herculeana*), giant ground beetle (*Calosoma helenae*) on Saint Helena, and probably other endemic invertebrates on Ascension.

One of the most dramatic examples of the impact of alien species on local terrestrial invertebrates was the deliberate introduction of the predatory snail *Euglandina rosea* to Hawaii, done with the intention to control another snail, a pestiferous African invasive *Lissachatina fulica*. What followed instead was rapid extinction of the majority of land snails in the endemic to Hawaii family Amastridae. A similar devastation of the native snail fauna by *E. rosea* took place in the Pacific Society Islands, where the large majority of the 61 described endemic Society Islands partulid tree snails (four *Samoana* and 57 *Partula* species) are now extinct in the wild (Lee *et al.*, 2009).

Overharvesting and Overcollecting

Few terrestrial invertebrates are commercially harvested, and thus the impact on their populations from harvesting is much lower than that on marine invertebrates. Coconut crab (*B. latro*) has become rare or locally extinct due to overharvesting on many islands of the Solomon Islands, and harvesting quota are now in place in other parts of its range, including Guam and Vanuatu (Figure 1). *Cornu aspersum*, *Helix pomatia*, and *Iberus* spp. are terrestrial snails frequently harvested for human consumptions throughout Europe. It is difficult to get reliable consumption numbers, but estimates for France, the main consumer, range between 20 and 40,000 t of snail meat being sold per year. While the first two species are not threatened, many species of *Iberus* are highly localized, and their overcollecting is bound to have negative impact on their populations (Cuttelod *et al.*, 2011).

Several species of katydids (Tettigoniidae) and crickets (Gryllidae) are collected and traded as singing or fighting insects in China. There is evidence that this trade is causing a reduction in the ranges and populations of some species as the demand for these insects occasionally reaches 100,000 specimens *per day* during the fighting season (Jin and Yen, 1998).

Collecting invertebrates for live pet trade has had some impact on populations of tarantulas and other arachnids. Malaysian trapdoor spiders (*Liphistius* spp.) have been locally overcollected and are now legally protected. Giant African scorpions (*Padinus* spp.) are also collected in massive numbers for the pet trade, and their exportation from the countries of origin is subject to strict quota.

International trade in a number of species of Birdwing butterflies (*Ornithoptera* and related genera) and South African Stag beetles (*Colophon* spp.) is now restricted, although most of the specimens of butterflies in the insect collector trade come from commercial captive breeding facilities. Overcollecting has led to at least one case of local species extinction: the British Large Copper Butterfly (*Lycaena dispar dispar*) appears to have been collected out of existence by 1848 (although this species is still widespread in other parts of Europe). Overall, however, there is little evidence of a negative

Figure 1 Coconut crab (*Birgus latro*) is the largest living terrestrial invertebrate, reaching the weight of up to 4.1 kg and leg span of up to a meter. These animals have been overharvested on many Pacific and Indian Ocean islands and disappeared from across some of their former range.

impact of collectors of insect and other terrestrial invertebrates on their survival, especially if compared to sweeping losses of species caused by deforestation and other anthropogenic impacts. Rather, insect collecting is often seen as a gateway activity to a greater awareness of environmental issues, and a valuable educational tool for the next generations of naturalists and conservationists (Naskrecki, 2005).

Status Assessment of Endangered Invertebrates

Despite the overwhelming majority of invertebrates in virtually all terrestrial habitats, or rather because of it, their diversity is not reflected proportionately in formal conservation efforts and documents. The assessment of invertebrate species endangerment is conducted by a mix of local, national, and international bodies and organizations, some of which have legal, executive power (e.g., federal list of endangered species in the USA), whereas others only provide recommendations for protection (e.g., IUCN Red Lists.) These lists use various, nonstandardized criteria for the assessment of the threat status of the invertebrates, and sometimes provide conflicting recommendations. Local lists (e.g., state lists in the USA, country-based Red Lists in Europe) frequently include species of invertebrates that appear threatened locally because their local occurrences are on the periphery of their range but are not threatened on the global or even country scale.

As of 2012, the IUCN Red List of Threatened species, the most prominent body that assesses the conservation status of species, includes 6113 species of invertebrates that can be classified as terrestrial, i.e., the species lives in a terrestrial environment during at least one phase of its developmental cycle. This includes 3844 species of insects, 2180 species of snails, 33 species of arachnids, 31 species of millipedes, 11 species of velvet worms, seven species of crustaceans, six species of earthworms, and one species of centipedes; overall the list includes less than 0.1% of the estimated number of terrestrial invertebrate species. In contrast, 34,779 species of vertebrates, or nearly 100% of known species, have been evaluated by the IUCN.

In addition to this global database of endangered species, local Red Lists are maintained by individual countries or regions (e.g., European Red List of Saproxyllic Beetles, Carpathian List of Endangered Species) (Nieto and Alexander, 2010; Witkowski *et al.*, 2003), but the coordination between country and global Red Lists is not perfect. For example, the Brazilian Red List of terrestrial invertebrates includes 130 species, many of which do not appear on the global Red List. This is despite the fact that most of these species are endemic to Brazil and thus endangered on a global scale (Lewinsohn *et al.*, 2005).

Comprehensive assessment of even a small fraction of the global invertebrate diversity is not feasible, and for this reason, a simplified methodology has been introduced to get an overview of their status. The Red List Index (sampled approach) (SRLI) has been developed in order to determine the threat status and trends of lesser-known and less “charismatic” species groups, such as several insect orders, and is based on a comprehensive assessment of a small subsample of members of such groups (e.g., only 10% of all known species of

Papilionoidea butterflies are being evaluated); the results are then used to interpolate the general trends within populations of all its members.

There appears to be, however, a number of biases in conservation assessment efforts for terrestrial invertebrate taxa, which may give a false picture of species distribution and abundance (Cardoso *et al.*, 2001). For example, species tend to be monitored more in places where high species richness is to be expected. The selection of taxa being monitored or evaluated is strongly skewed toward “charismatic” and easily identifiable groups, such as butterflies, but these groups are typically species-poor and may not be representative of invertebrates as a whole. There is also a tendency to overestimate the overall species’ rarity based on regional occurrence, which often falls on the margins of the species’ range.

The Convention on International Trade in Endangered Species (CITES) is a multilateral treaty designed to ensure that international trade in specimens of wild animals and plants does not threaten the survival of the species in the wild, and it accords varying degrees of protection to more than 33,000 species of animals and plants. It currently lists 348 species of terrestrial invertebrates, albeit there is little correspondence between the CITES list, which has executive power to control the international trade in these organisms, and the IUCN Red List, which ranks species according to relatively rigorous criteria of current or potential threat. For example, of the 23 species of spiders listed by CITES, only one appears on the IUCN Red List (categorized as Lower Risk); conversely, of the 25 species of spiders listed as threatened by the IUCN, none is listed by CITES.

Approaches to Terrestrial Invertebrate Conservation

Coarse and Fine Filters in Invertebrate Conservation

The concept of conserving entire plant and animal communities in reserves was originally viewed as an efficient coarse filter approach to conserving biodiversity that would protect 85–90% of all species. This was based on the assumption that carefully selected areas, often containing so-called “umbrella species”, will preserve enough habitat heterogeneity to sustain a large selection of unrelated taxa. More recently, the coarse filter has evolved to a concept of conserving species diversity by providing adequate representation (distribution and abundance) of ecological land units based on an understanding of their natural disturbance regimes. This coarse filter approach does not necessarily prescribe reserves but rather recognizes ecological processes and provides for a dynamic distribution of ecological units across the landscape over time (Samways, 2005). The reality of a matrix of agricultural landscapes and high fragmentation of the remaining natural habitats across most of Europe and many other developed areas makes it necessary to develop conservation strategies that focus on management and restoration of what remains. In the UK, landscape-scale conservation projects are now the main delivery mechanism to conserve its threatened Lepidoptera. It is achieved by providing advice to landowners and assistance with obtaining agri-environment or woodland grant schemes, and by habitat

management under the guidance of the UK’s Butterfly Conservation organization (Ellis *et al.*, 2011).

The complementary fine filter approach focuses on conserving individual rare or specialized species that slip through the coarse filter and are not necessarily protected in reserves. The Red List assessments are designed to pinpoint such species, and its fine filter assessments are conducted to evaluate whether sufficient amount and distribution of habitat is provided under the coarse filter strategy.

The creation in 1978 of the Tripuí Reserve in Minas Gerais province of Brazil to protect the population of a velvet worm (*Peripatus acacioi*) is an example of a conservation action based on a fine filter assessment of the status of a single species.

Surrogates in Terrestrial Invertebrate Conservation

Plants have long been used as environmental surrogates for invertebrate diversity, particularly that of insects. Because they are easier to identify and map than invertebrates, and there is an unquestionable dependence of most insects on their existence, species-rich plant communities can be used to designate protected areas with expectedly high levels of invertebrate diversity. It has been shown that species richness of even those invertebrates that do not directly rely on any particular plant species, such as dragonflies, is positively correlated with plant diversity. Plants have also been demonstrated to be much better predictors of invertebrate diversity than vertebrates. At the same time, there exist confounding issues, and spatial distribution of insects does not necessarily overlap completely with that of plants; for example, although there is a strong relationship between the distribution of butterflies and leaf-hoppers, and that of tallgrass prairie plants, no such correlation was found between other prairie plants and other insects. This suggests that focus on “hotspots” of plant diversity may not include many insect species at finer scales.

Plant surrogacy approaches usually emphasize indigenous vegetation, but in the absence of that, even exotic plants may provide suitable habitats for native invertebrate faunas: in the Azores exotic forests have provided alternative habitats suitable for native saproxylic beetles, whereas in South Africa pine plantations turned out to provide sufficient habitats for velvet worms (*Opisthopatus cinctipes*) that used to inhabit indigenous, but now largely gone coastal forests (Hamer *et al.*, 1997). Also in South Africa, organic vineyards have the potential to make an important contribution to arthropod conservation in the Cape Floristic Region at the field scale, although at landscape scale, the preservation of natural fragments in the vineyard landscape is the most effective measure to increase biodiversity.

Animals, and birds in particular, have been used as surrogates for invertebrate distribution and richness. At some spatial scale, birds and butterflies show similar trends in species richness and diversity. In Uganda, the selection of potential forest reserve sites based on either birds or butterflies was as effective at representing other taxa as the selection based on the richness of plants and a wide range of animal taxa. In the Azores species richness of four groups of endemic arthropods was a good predictor of overall species richness (Borges *et al.*, 2010), but in other parts of the world vertebrate or

single-taxon invertebrate distribution does not correlate strongly with that of invertebrates in general and may give a misleading picture of the overall biodiversity of an area.

“Umbrella” Species

“Umbrella” or “flagship” species are species whose conservation is assumed to correlate positively with protection of other, unrelated species, or communities. This concept has been widely applied in the designation of nature reserves, despite the fact that little proof exists for the effectiveness of this approach in protecting broader biodiversity. There is some evidence that it may be effective in fine filter, species-level approaches to conservation of individual invertebrate communities, for example, European beetle *Osmoderma eremita* serves as a suitable umbrella species for other beetles associated with tree hollows.

Recovery Programs

Terrestrial invertebrate recovery can be conducted on both coarse- and fine-filter scales. Coarse filter approaches focus on restoration of habitats, such as the effort to restore stone cover and reduce grazing in French pseudo-steppe, which resulted in a great increase in the abundance and species richness of beetle species. Conversely, restoration of grazing in areas where plant succession eliminates savannah-like, open habitats often results in the increase of the species richness of native pollinators and other invertebrates.

At the species level, translocation of New Zealand wetas (*Deinacrida* spp.) to areas where invasive rats were eliminated has proven quite successful in restoring their populations (Stringer and Chappell, 2008). Captive breeding programs have been used to restore populations of locally declining or extinct species, although such programs can only be used for species with relatively simple life histories (Samways et al., 2010). The Lord Howe Island stick insect (*Dryococcus australis*) had been thought to be extinct until a small population was found on a tiny Ball’s Pyramid Islet (New 2012); a small fraction of the population has been collected and is now successfully breeding in captivity at Melbourne Zoo, although the captive animals have not yet been reintroduced into the wild. In the UK, two species of the Orthoptera, field cricket (*Gryllus campestris*) and wart biter katydid (*Decticus verrucivorus*), are captive bred and have been reintroduced to their former, suitable habitats. (Figure 2).

Endangered Terrestrial Invertebrates Listed by the Global IUCN Red List and CITES

Of the approximately 12 currently recognized classes of invertebrates that include terrestrial or partially terrestrial species, eight classes include species whose level of endangerment has been evaluated by the IUCN Red List. This includes species assigned to the following threat categories: extinct – 261 species, extinct in the wild – 12 species, critically endangered – 299 species, endangered – 347 species, vulnerable – 836

Figure 2 European wart biter katydid (*Decticus verrucivorus*) virtually disappeared across its former range in Britain and has been subject to an experimental captive breeding program. Although the program was successful and the katydids were subsequently reintroduced to their natural habitats, captive breeding of this species is costly and labor intensive.

species, near threatened and least concern – 3036 species, and data deficient – 1359 species.

Earthworms (Oligochaeta)

The IUCN Red List includes eight species of earthworms, of which four are listed as vulnerable and one as extinct; no species of earthworms are listed by CITES. Earthworms are threatened primarily by habitat loss and agricultural development; the population of the Australian Giant Gippsland Earthworm (*Megascolides australis*) has apparently declined following the switch from cattle ranching to crop-based agriculture. The Giant Palouse Earthworm (*Driloleirus americanus*) of NW USA is considered vulnerable due to habitat loss but also because of the competition from nonnative, introduced species of earthworms. In Europe and the USA, the invasive New Zealand planarian (*Artioposthia triangulata*) that feeds on earthworms has apparently caused a decline of native species.

Velvet Worms (Onychophora)

Eleven species of these distant relatives of arthropods are considered threatened on the global scale by the IUCN Red List, although additional species appear on local, country, or regional lists. Velvet worms are threatened by several factors. In Tasmania, government-mandated planned fires have led to local extirpation of several endemic species and may eventually contribute to their extinction. Overcollecting of these animals to meet the demands for teaching specimens for invertebrate zoology classes at Australian universities has apparently caused local declines, whereas in South Africa urbanization of native habitats has caused decline, and perhaps extinction of species. Conversely, in Brazil, a local nature reserve was created to protect the endemic species *P. acacioi* (Figure 3).

Figure 3 Velvet worms (Onychophora), like this individual from Daintree Rainforest of Queensland, Australia, include many narrowly endemic species with specific microhabitat requirements. Several species of these animals are probably already extinct, whereas many others are known only from single, small populations.

Spiders, Daddy Longlegs, and Pseudoscorpions (Arachnida)

Thirty-three species of arachnids are listed, 30 of which are spiders. Many have been placed on the list because they are narrow range endemics (e.g., species restricted to single caves), rather than because of a demonstrable decline in their population sizes. Several tarantula species, such as the Indian *Haplocastus kayi*, are restricted to very few locations in a rapidly shrinking natural habitat. Interestingly, there exists the overlap of only one species, Red-knee tarantula (*Brachypelma smithi*), between the IUCN Red List and CITES; the latter includes 22 species of tarantulas and three species of scorpions, all threatened by collecting for the exotic pet trade.

Centipedes (Chilopoda)

Only one species, Serpent Island Centipede (*Scolopendra abnormis*), is listed by the IUCN Red List, and no species are on the CITES list. This species is endemic to Mauritius and considered vulnerable.

Millipedes (Diplopoda)

The IUCN Red List includes 31 species of millipedes, all placed in the southern African genus *Doratogonus*. They are threatened mostly by the habitat loss caused by the extraction of wood by the local community for fuel and building.

Crabs, Pillbugs, and Woodlice (Crustacea)

Seven species of terrestrial crustaceans are listed by the IUCN Red List. The largest terrestrial invertebrate, Coconut crab (*B. latro*) from the Pacific and Indian tropical islands, is listed as Data Deficient, although there is evidence of its decline and local extirpation on some islands. The remaining six species are woodlice (Isopoda) with narrowly restricted ranges.

Insects (Insecta)

Insects constitute the majority of terrestrial invertebrates listed by the IUCN Red List, with 3844 species. Most of them are dragonflies and damselflies (2657 species), threatened by the disappearance of suitable, unpolluted aquatic habitats required for the development of their larval stages. Butterflies and moths are represented by 720 species; most are threatened by habitat loss and fragmentation, climate change, increased frequency and intensity of fires, and tourism development; some species are threatened by collecting for trade in preserved butterflies. Beetles are represented by 220 species, mostly those with narrow, endemic ranges and few known populations; some species, such as the American burying beetle (*N. americanus*) or violet click beetle (*Limonicus violaceus*), have extensive ranges but are known only from small, widely scattered relict populations. The presence of the Pygmy Hog Sucking Louse (*Haematopinus oliveri*) from India on the list illustrates the point that the decline of the host organism's populations; in this case, the Critically Endangered Pygmy Hog (*Porcula salvania*) leads to the decline of their symbionts.

CITES lists 271 insect species and subspecies, primarily narrow endemics or species threatened by overcollecting.

Land Snails (Gastropoda)

This is the second best represented group on the IUCN Red List, with 2180 evaluated species. This includes virtually all endemic snails from Hawaii and the Society Islands (many of which are now considered extinct), decimated by the introduction of alien, predaceous snail *E. rosea*. A large proportion of the snails listed here are also European endemics, often restricted to small Mediterranean islands and threatened by urbanization and tourism industry. The CITES list includes 51 species of Pacific island land snails.

Glossary

Diptera Group of insects to which the flies, including gnats and mosquitoes, belong.

Larva (pl. larvae) Immature stage of flies, often called maggots.

Introduction

The insect Order Diptera, with more than 124,000 currently described, extant species, ranks as one of the worlds largest groups of organisms. Along with the other insect megadiversity groups—Coleoptera (beetles; 350,000 species), Lepidoptera (butterflies and moths; 120,000 species), and Hymenoptera (ants, bees, wasps, and sawflies; 130,000 species)—they form the largest aggregation of species on the planet. Each of these megadiversity groups has more species assigned to it than to any other group of organisms except plants (300,000 species). Like other insects, most species of Diptera are still undescribed, and the actual number could range as high as 1 million or more species.

Diptera are found on every continent, including Antarctica. The relative percentage of Diptera within the insect fauna rises with latitude (and elevation) as other, less cold-adapted taxa are lost; for instance, over one-half of all insect species recorded from the Canadian high arctic are Diptera. The extant species of all biogeographical regions have been cataloged (Table 1), as have the fossil Diptera. Some catalogs are badly outdated and the number of species described for each region is often more indicative of the amount of taxonomic activity directed at a given fauna than the true diversity. For instance, the Palearctic Region is the best studied and has more described species than the relatively poorly known, but presumably more diverse, Neotropical Region. Therefore, conclusions about dipteran biogeography based on these numbers will be highly inaccurate.

Diptera are a well-established monophyletic group, with the most obvious defining character being the reduction of the hind wings to small, club-shaped organs called halteres. The

insect orders considered to be most closely related to Diptera are Siphonaptera (fleas) and Mecoptera (scorpionflies), although recent molecular research indicates that the highly aberrant Strepsiptera (twisted-wing parasites) may be their closest relatives.

Fossil Diptera are common in the amber faunas of the world, which however extend back in time only to the early Cretaceous. The oldest dipteran fossil is believed to be from at least the mid-Triassic.

Like the other megadiversity groups, the Diptera are holometabolous insects, with a separate egg, larva, pupa, and adult stage. Generally, most feeding takes place in the larval stage, whereas the adult is usually specialized for reproduction and dispersal. Some adult Diptera are voracious feeders, however, requiring substantial supplemental feeding to mature their eggs or power their flight.

Flies are common in natural, disturbed, and urban habitats. Larvae are found on land and in freshwater; there are relatively few marine or brackish water species. Some species are synanthropic and have been transported around the world with human activities. Diptera are the most important vectors of human and animal disease, and a few plant-feeding species have become agricultural pests. The life history of most species of flies, however, is unknown. The group is so large, and there are so many undescribed species, that the science of dipterology is still in its relative infancy.

Major Subdivisions

Table 2 presents a general list of the families of Diptera and some of the higher taxa that contain them. This list is based on only one of several possible classifications, however, and cannot be considered the final word in dipteran groupings. Common names, where well established, are given in Table 2. Many families lack common names, including the second largest family in the order (Tachinidae). That a group with more described species than the mammals lacks a common name is a good indication of the lack of general appreciation for the importance and ubiquity of the Diptera. The number of described species in each family is given, but in many instances these numbers are badly out of date and should be considered a bare minimum. Certainly, in most families of Diptera there are a large number of undescribed species awaiting the attention of specialists. It is estimated that we

Table 1 Biogeographical regions and the number of described diptera species

Region	Number of species
Nearctic	25,000
Neotropical	20,000
Palearctic	29,000
Afrotropical	16,318
Australasian	15,764
Oriental	15,964
Antarctica	60

Compiled from the various catalogs.

Table 2 Simplified list of major subgroups and families of Diptera

	<i>Common name</i>	<i>Number of species</i>
Lower Diptera (= Nematoceros groups)		
Infraorder Ptychopteromorpha		
Ptychopteridae	Phantom crane flies	61
Tanyderidae		42
Infraorder Culicomorpha		
Superfamily Culicoidea		
Culicidae	Mosquitoes	3,000
Dixidae	Meniscus midges	175
Corethrellidae		61
Chaoboridae	Phantom midges	50
Superfamily Chironomoidea		
Ceratopogonidae	Biting midges	5,360
Chironomidae	Midges	5,000
Simuliidae	Black flies	1,475
Thaumaleidae		121
Infraorder Blephariceromorpha		
Blephariceridae	Net-winged midges	300
Deuterophlebiidae	Mountain midges	14
Nymphomyiidae		7
Infraorder Bibionomorpha		
Axymyiidae		5
Bibionidae	March flies	675
Cecidomyiidae	Gall midges	4,600
Mycetophilidae	Fungus gnats	3,000
Pachyneuridae		4
Sciaridae	Dark-winged fungus gnats	1,000
Infraorder Tipulomorpha		
Tipulidae	Crane flies	14,000
Trichoceridae	Winter crane flies	110
Infraorder Psychodomorpha		
Anisopodidae	Wood gnats	100
Perissomatidae		5
Psychodidae	Sand flies, moth flies	2700
Scatopsidae		255
Synneuridae		4
Brachycera (an unranked taxon)		
Infraorder Xylophagomorpha		
Xylophagidae		111
Infraorder Tabanomorpha		
Athericidae		90
Pelecorhynchidae		49
Rhagionidae	Snipe flies	520
Tabanidae	Horsetflies, deer flies	3,000
Vermileonidae	Ant lions	31
Infraorder Stratiomyomorpha		
Pantophthalmidae		20
Stratiomyidae	Soldier flies	2,500
Xylomyidae		107
Infraorder Muscomorpha		
Superfamily Nemestrinoidea		
Acroceridae	Small-headed flies	500
Nemestrinidae	Tangle-veined flies	250
Superfamily Asiloidea		
Apioceridae	Flower-loving flies	145
Asilidae	Robber flies	5,600
Bombyliidae	Bee flies	4,800
Mydidae	Mydas flies	353
Scenopinidae	Window flies	330
Therevidae	Stiletto flies	850

Source: Adapted from Yeates DK and Wiegmann BM (1999) Congruence and controversy: Toward a higher-level phylogeny of Diptera. *Annual Review of Entomology* 44: 397–428, and McAlpine JF (ed.) (1989) *Manual of Nearctic Diptera*, vol 3. Agriculture Canada Monograph No. 32.

Most important taxa are in bold. Approximate number of described species from various sources.

have described only 10% or fewer of the species in many families.

The Diptera are traditionally organized into three suborders: the Nematocera, the orthorrhaphous Brachycera, and the cyclorrhaphous Brachycera. Of these, it is likely that only the Cyclorrhapha is a monophyletic, or natural, group.

Although a consensus on the higher relationships within the Diptera is not yet available, it is generally agreed that the “Nematocera” is a paraphyletic assemblage of relatively primitive dipteran families and that some subgroup of this assemblage is more closely related to the Brachycera than to other nematocerans. Similarly, within the Brachycera, a group

widely considered to be monophyletic, the orthorrhaphous families are now believed to be a paraphyletic assemblage relative to the Cyclorrhapha. Finally, within the Cyclorrhapha is a group of flies traditionally called the Aschiza (here called the lower Cyclorrhapha), which is probably paraphyletic with respect to the monophyletic Schizophora. The details of the phylogeny of the Diptera has been reviewed extensively by Yeates and Wiegmann and their discussion of various groups is highly recommended for understanding the current status of dipteran phylogeny.

Within the Diptera, higher taxa show repeated patterns of relatively primitive, nondiverse grades of organization with relatively highly derived, speciose sister taxa. Thus the lower Diptera are collectively much less diverse than the Brachycera, with the notable exception of the incredibly large family Tipulidae. Within the Brachycera, the Muscomorpha is by far the largest infraorder and the Schizophora has four times more species than the lower Cyclorrhapha. The numbers are less disparate in the Schizophora, with about 26,000 acalyptrates and 19,000 calyptrates, but the monophyly of the acalyptrates is highly contentious, making such a comparison questionable.

The distribution of species among the families of Diptera is extremely divergent, with the largest number found in the Tipulidae and the Tachinidae. Together, these families account for almost 20% of the species in the order.

The Tipulidae, or crane flies, are elongate, long-legged, somewhat fragile flies that are found nearly everywhere on earth. The adults are sometimes found at lights but are most often seen resting on vegetation. The larvae have a variety of habitats, including terrestrial—in soil, mosses, and decaying wood—freshwater, and intertidal. They are scavengers, herbivores, or predators.

In contrast to the eclectic habits of the Tipulidae, larvae of Tachinidae have a single way of life: parasitism. All known species are internal parasitoids of other arthropods, mostly other insects and, within the insects, mostly larval Lepidoptera. Eggs are either laid on or in the host or are broadcast in suitable areas. Larvae hatch from broadcast eggs and wait in ambush for hosts. Some tachinids produce microtype eggs that are designed to be ingested by the hosts; these eggs hatch inside the host and penetrate the gut wall to enter the body cavity. Adult tachinids are stout, bristly, housefly-like flies that are seen frequently on vegetation or flowers.

There are another 21 families of Diptera that can be considered large, possessing about 2000 or more described species. Together, these 23 largest families (including tipulids and tachinids) comprise about 100,000 species, or approximately 80% of the Order Diptera. In order of decreasing number of species, these other 21 large families are as follows:

- Syrphidae: hover flies, flower flies (5800 spp.). Adults of this family often are brightly colored mimics of Hymenoptera (bees and wasps). The larvae are saprophagous, predatory, or herbivorous. Some saprophagous species are called rat-tailed maggots because of their elongate posterior breathing tubes. Many of the predatory species live exposed on plants, feeding on aphids.
- Asilidae: robber flies (5600 spp.). The adults are voracious predators that usually attack their prey while in flight, stabbing them with their heavily sclerotized, swordlike

proboscis and injecting digestive fluids. The larvae are also predatory.

- Ceratopogonidae: biting midges (5360 spp.). The tiny adult females of this family require blood meals to mature their eggs. Some species bite vertebrates, other feed on large insects, and still others are predatory on small insects. The larvae are predacious, living in damp terrestrial or freshwater habitats.
- Dolichopodidae: long-legged flies (5100 spp.). These flies are often metallic green in color and are found commonly on undergrowth or on tree trunks. The larvae and adults are predatory.
- Chironomidae: midges (5000 spp.). These flies are among the most abundant benthic invertebrates in freshwater environments; some are also terrestrial or intertidal. The adult males often form enormous mating swarms.
- Bombyliidae (including Mythicomyiidae): bee flies (4800 spp.). Species of this family are most diverse in dry areas, including deserts, and are nearly absent from tropical rain forests. The larvae are parasitoids of the immature stages of various other insects or predatory on grasshopper egg pods.
- Cecidomyiidae: gall midges (4600 spp.). Cecidomyiids are generally considered one of the largest, yet most poorly known groups of Diptera. Larvae often form galls on various plants, but there are non-gallforming species and many mycophagous forms as well.
- Tephritidae: fruit flies (4000 spp.). Larval tephritids are phytophagous, attacking a wide variety of plants and sometimes forming galls. The adults often have color patterns on their wings.
- Muscidae: houseflies and relatives (3880 spp.). A few extremely well-known muscid species are synanthropic, especially *Musca domestica* and *Stomoxys calcitrans*. Larvae of most species live in decaying organic material, where they are either saprophagous or predatory. Some species are saprophagous in early larval instars, becoming carnivorous later.
- Agromyzidae: leaf-miner flies (3500 spp.). Along with some other insects, larvae of many species of agromyzids feed within plant leaves, excavating the distinctive, light-colored tunnels called mines. The adults are small, usually dark-colored flies; some species are marked with yellow.
- Empididae: dance flies (3500 spp.). Adults of this family are found mostly in damp terrestrial habitats, often near water. Common and diverse in temperate regions, they are less prevalent in tropical lowland forests. Larvae and adults of both sexes are predatory; larvae of a few species are parasitoids of caddisfly larvae.
- Phoridae: humpbacked flies, scuttle flies (3200 spp.). Phorids are common and diverse nearly everywhere except Antarctica. Larvae can be predators, parasitoids, true parasites, herbivores, or scavengers. Many species are associated with social insects.
- Tabanidae: horseflies, deer flies (3000 spp.). Adult female tabanids are well-known blood feeders, although some species feed only on nectar. The larvae are predatory, usually found near water.
- Culicidae: mosquitoes (3000 spp.). Adult females bite vertebrates to obtain blood meals, and they often transmit diseases. Larvae are aquatic.

- **Mycetophilidae:** fungus gnats (3000 spp.). Adults are found mostly in humid, forested areas. The larvae feed mainly on fungi, although some species spin webs to capture insect prey and a few species are parasitoids of flatworms.
- **Drosophilidae:** vinegar flies, pomace flies (2900 spp.). This family is best known for *Drosophila melanogaster*, the ubiquitous model organism for genetic research. Although adults are commonly found around overripe fruit or on mushrooms, the larvae of this family have a variety of lifestyles, from saprophagy to parasitism and predation.
- **Psychodidae:** moth flies (2700 spp.). The scavenging larvae of these flies are usually found in moist conditions, in soil, rotting wood, or other decaying vegetation. Adults of one subfamily are blood feeders and transmit the disease leishmaniasis to humans.
- **Sarcophagidae:** flesh flies (2500 spp.). Sarcophagid larvae are saprophagous, parasitoids, predators or commensals in the nests of solitary Hymenoptera. The adults of some species are associated with filth.
- **Sphaeroceridae:** lesser dung flies (2500 spp.). Larvae and adults of this family are commonly found on dung, carrion, and decaying organic material.
- **Stratiomyidae:** soldier flies (2500 spp.). The adults of this family are often brightly colored and conspicuous on flowers. The larvae are often found near water, in decaying organic material, or under bark. They are saprophagous, herbivorous, or predatory.
- **Chloropidae:** frit flies (2000 spp.). Larvae of chloropids have nearly every conceivable way of life, from scavenging to predation, parasitism and herbivory, although there are many more plant feeders in this family than the similarly diverse Phoridae.

Nematocerous Families

The nematocerous families are the relatively primitive members of the Diptera, characterized by long, unconsolidated antennae consisting of many segments. There are 26 families in this group and approximately 40,000 species included. Many are associated with aquatic habitats and some, such as mosquitoes, black flies, and biting midges, are voracious blood feeders.

Brachycera

Most Diptera belong to the Brachycera, a group characterized by the reduction or fusion of antennal segments to eight or fewer and by modifications to the larval head and mouthparts. With about 80,000 described species, this group contains many of the best known flies, such as houseflies and fruit flies.

The lower Brachycera includes several lineages constituting approximately 30,000 species. The larvae of most species are predatory, although there are a few parasitoid groups as well. The most familiar are the large families Asilidae, Bombyliidae, Tabanidae, Dolichopodidae, and Empididae.

The Cyclorrhapha, with about 50,000 species, includes a few primitive lineages and the Schizophora. The primitive groups are relatively small, with the exceptions of the large

families Phoridae and Syrphidae. Within the Schizophora, there are a plethora of smaller acalypterate families that are rare, but many, such as the Tephritidae, Agromyzidae, Drosophilidae, Sphaeroceridae, and Ephydriidae, are abundant and commonly encountered. The Calyptratae includes the familiar houseflies, flesh flies, and blow flies as well as the speciose parasitoids of the Tachinidae. Also included are a number of mammal parasites, including some truly bizarre, spider-like bat parasites in the Nycteribiidae and Streblidae.

Life History Diversity

Larvae

The larvae of flies are abundant and widespread in most terrestrial and aquatic habitats. They are often encountered in soil (including sand), dead wood, dung, carrion, decaying vegetation, and among the refuse of social insect colonies. Relatively few are found living exposed on vegetation, including some herbivorous tipulids and many aphidophagous syrphids. Aquatic forms are found on the bottom and in the water column of lakes, streams, and ponds. Larval Diptera are predators, scavengers, herbivores, parasitoids, or even true parasites.

Scavengers

This is the lifestyle most commonly associated with Diptera larvae, especially those of the Brachycera. More than half of the 128 families recognized herein have larvae that feed on decaying organic material or organic detritus. Most receive their nutrition from bacteria and other microorganisms of decay, not from the main substance on which they are found. They concentrate these organisms and other suspended particles with a sievelike pharyngeal filter.

Among the most obvious terrestrial scavengers are the larvae of blow flies (Calliphoridae) that are found on newly dead animal carcasses. Early stages of decay are characterized by large numbers of calliphorid and muscid larvae, followed later by drosophilids, fanniids, phorids, piophilids, sepsids, sphaerocerids, and others as decay proceeds. The fauna of buried carrion is different, with the calliphorids largely excluded. Instead, the muscid genus *Muscina*, various phorids, and sphaerocerids predominate. The fauna of carrion immersed in water has also been studied and found to differ from that on dry land. There has been considerable study of the succession of scavenging Diptera larvae on dead animals, leading to the potential for their use in forensic entomology.

Decaying vegetable matter is also rich in scavenging Diptera, especially muscids, sphaerocerids, sciarids, and others. Some muscids are obligate thermophiles, requiring the heat generated by the decay of large piles of compost. Decaying seashore vegetation supports coelopids, sphaerocerids, and anthomyiids. Rotting fruit is the food of drosophilids, stratiomyids, and some phorids.

In aquatic environments, many larval Diptera feed on small organic particles in the water or on the substrate. Larvae of Culicidae and Simuliidae filter particles from the water with their brushlike labral fans.

Herbivores

Diptera that feed on living plants (including algae and fungi) are found in 37 of the 128 families recognized herein. Some, such as Agromyzidae, Anthomyiidae, Bibionidae, Cecidomyiidae, Chloropidae, Phoridae, Psilidae, Sciaridae, Tephritidae, and Tipulidae, include species considered to be pests to human agriculture. Fly larvae attack all parts of plants, including fruits, flowers, stems, leaves (as leaf-miners), and roots.

Predators

Predators are organisms that kill more than a single host organism for their feeding. There are 35 families with this way of life, including nearly all of the noncyclophoraphan Brachycera. Most have extremely active larvae that attack other invertebrates as their major food source. The larvae of tabanids have been known to kill frogs, an interesting reversal of the usual chain of events. Many predatory dipteran larvae are beneficial to humans in controlling insects considered to be pests. Examples include syrphids attacking aphids and predatory muscid larvae that kill larvae of other muscids, such as houseflies.

Parasitoids

Parasitoids develop on and kill a single host. Twenty-two families of Diptera have this way of life, which was reviewed recently by Feener and Brown. All species of the second largest family of Diptera, the Tachinidae, are parasitoids. All dipteran parasitoids attack other invertebrates, usually other insects, but unusual hosts include terrestrial flatworms, mollusks, earthworms, millipedes, spiders, and scorpions.

Parasites

Parasites feed on a single host, but do not normally kill it. True parasites include the bot flies, whose larvae live under the skin or in the nasal cavities of various mammals, including humans. Some bot fly larvae live in the stomachs and alimentary tracts of horses, elephants, zebras, and rhinos. Other parasites of vertebrates are calliphorids, chloropids, piophilids, and muscids. True parasites of invertebrates are less well known but occur in a few families, such as Phoridae.

No Free-Living Larvae

The larvae of the four families of the Hippoboscoidea—Glossinidae, Hippoboscidae, Nycteribiidae and Streblidae—are retained in the female abdomen and nourished by secretions of the accessory glands. They are deposited by females as fully mature, third-instar larvae, which quickly pupariate.

Adults

Most adult Diptera receive the majority of their nutrition as larvae and do not feed extensively. Many need carbohydrates to power their flight, however, and feed on the nectar in flowers, or on honeydew, the sweet secretions of Homoptera. Some flies require nitrogen for nourishing their eggs and are thus avid flower visitors in search of pollen. Flower foraging for nectar and pollen makes Diptera adults important pollinators of plants.

At least some parasitoids feed on the hemolymph of their hosts after oviposition, and many dipteran species feed on dead insects, carrion, dung, or rotting vegetation. A few adult Diptera, including Deuterophlebiidae and some Oestridae, have vestigial mouthparts and do not feed.

Adults of a number of families have species that are well-known blood feeders, especially most or all species of Ceratopogonidae, Culicidae, Glossinidae, Hippoboscidae, Nycteribiidae, Simuliidae, Streblidae, and Tabanidae. Other families with fewer blood-feeding species are Muscidae, Rhagionidae, and Athericidae.

Some families of Diptera have species that are predatory as adults. This lifestyle is especially well developed in the Asilidae, Dolichopodidae, and Empididae but also occurs in some other families, such as Muscidae and Phoridae.

Special Associations**Aquatic Diptera**

The larvae of many nematoceros families, as well as some Brachycera, are found in freshwater habitats. Among the most consistently aquatic forms are those families in the Culicomorpha and Blephariceromorpha, including such well-known families as Culicidae (mosquitoes), Simuliidae (black flies), and Chironomidae (midges). Chironomidae in particular can be exceedingly abundant, and various species assemblages are often used for assessment of water quality. The larvae of Simuliidae and Blephariceromorpha are found almost exclusively in clean, running water, with the Deuterophlebiidae and Blephariceridae being especially adapted to fast-flowing streams. Larval Culicidae are often found in ephemeral ponds that appear after snowmelt in temperate regions and after heavy rains elsewhere.

Phytotelmata

Phytotelmata are structures of plants that allow accumulations of water. They occur in various parts of plants, including leaves, leaf axils (especially of bromeliads and bananas), stems (especially of bamboos), fruits, and specialized structures (such as pitchers in pitcher plants). Among the approximately 20 families of Diptera that utilize phytotelmata, the Culicidae are the most prominent, being the most regular and most numerous larvae present. The other most frequently encountered families are Chironomidae, Ceratopogonidae, and Psychodidae, but further research has found that other families, such as Phoridae and Tipulidae, might also be common. Our knowledge of the fauna of phytotelmata is still fragmentary and much further work needs to be directed at these habitats.

The insect trapping structures of pitcher plants (Nepenthaceae and Sarraceniaceae) frequently harbor dipteran larvae. For instance, a distinctive fauna of about 80 species of aquatic Diptera is specialized to live in the carnivorous pitcher plants of the genus *Nepenthes* in Southeast Asia. The species found in this habitat are mostly from aquatic groups, such as mosquitoes, but some are from families more usually found in terrestrial habitats—Calliphoridae, Chloropidae, and Phoridae, for example. Nearly all feed on the trapped, drowned

insects, or filter microorganisms associated with the decay of such insects from the water.

Social Insects

Social insects are the ants, bees, wasps, and termites that have organized societies. They have one or a few females responsible for all the egg laying, while other members of the colony (usually sterile females) gather food and do other tasks. Diptera are associated with social insects as scavengers, predators, parasitoids, and parasites. In the following treatment, only those species intimately associated with social insects are discussed, whereas opportunistic, generalized predators, such as robber flies (Asilidae), will be ignored.

Most flies known to be associated with social insects are brachycerans. Among the few nematocerous records of such associations is the astonishing observation that some Southeast Asian mosquito adults (genus *Malaya*) feed on honeydew carried in the mouthparts of ant workers.

Among the Brachycera associated with social insects, the most diverse are the Phoridae. These small flies are commonly found in association with ants, especially army ants (both New World and Old World), termites (especially in Africa and Southeast Asia), and, to a lesser extent, social bees and wasps. Many are parasitoids, laying their eggs inside the bodies of their adult hosts, usually ants, termites, and stingless bees; some are also known to parasitize the immature stages of ants. Many are scavengers, living in the refuse piles of the large colonies of army ants and leaf-cutter ants, where they are joined by scavenging larvae of other families. Some phorid larvae are predatory on ant brood, as are the larvae of some syrphids. The females of phorid species living in social insect nests are often remarkably modified, with reduced wings, eyes, and body sclerotization. One remarkable genus from Southeast Asia has adult females that mimic the larvae of their army ant hosts. Other females are heavily armored and have a rounded, teardrop shaped body form. This limuoid body form allows the females to escape damage when accosted by aggressive host ants, bees, or termites.

Other dipteran larvae found in social insect nests belong to the families Braulidae, Calliphoridae, Fanniidae, Sarcophagidae, Sphaeroceridae, and Syrphidae. Most are scavengers, although some are predatory.

Army ant raids are spectacular tropical phenomena that provide a number of opportunities for dipteran associates. Tachinids and conopids hover or perch near the raid front, darting down to parasitize the crickets, cockroaches, and other insects flushed by the foraging ants. Closer to the ground, parasitic phorids dart at their respective hosts: either the army ants themselves or other ants that are victims of the ant raids. Sarcophagids swarm on the leaves of nearby undergrowth, feeding on the droppings of birds attracted to the insects flushed out by the ant raids. Often, the raid front is best identified by listening for the loudest buzzing from the activity of hundreds of flies.

Kleptoparasites

Many Diptera exploit other insects or invertebrates that sequester or reserve food for long periods of time. By waiting before feeding, or by feeding slowly, these hosts provide a window of opportunity for larvae or adults of flies. The relationship between the host and kleptoparasite is often developed to such an extent

that the flies live permanently associated with their food provider. Phoresy (transportation of the kleptoparasite by the host) often occurs in these associations.

A commonly observed example of kleptoparasitism and phoresy in Diptera is the association of large spiders and flies. Spider webs provide a continuous supply of food, and often a source of stored insect carcasses for later feeding. This warehouse is exploited by a number of fly families, including Ceratopogonidae, Cecidomyiidae, Milichiidae, Chloropidae, Lonchaeidae, Phoridae, and Empididae. In many instances, the flies perch on the bodies of the spider, waiting for their next meal to arrive.

Another, much more restricted association occurs between dung beetles of the family Scarabaeidae and flies of the family Sphaeroceridae. The flies ride on the bodies of the dung beetles, waiting until the beetles find and bury feces for their own larvae to feed upon. The flies briefly hop off the beetles, lay their own eggs on the dung, and then rejoin their food-providing host.

Kleptoparasites also occur in the nests of social Hymenoptera, where fly larvae are fed by deceived workers or attack the provisions left for a developing bee, wasp, or ant larva. A full review of kleptoparasitism is given by Sivinski *et al.* (1999).

Swarming

Swarms of adult Diptera are a common sight in most environments. Usually these are aggregations of males, allowing females to easily find a mate. Often, swarms are seen in the canopy of forests, under overhanging branches, in sunlight "pools" in forests, near fire towers emerging above tree level, or at the summit of tall hills or mountains ("hill-topping").

Most nematocerous families engage in swarming, as do about 15 families of Brachycera. Flies that engage in this behavior often have associated structural modifications, including a well-developed anal lobe of the wing and enlarged compound eyes. The development of the anal lobe probably allows for better maneuvering and hovering within the swarm, whereas the increased size of the eye allows male flies to more precisely place themselves, and assess their place, within the swarm. As females choose dominant males within the swarm, based on their relative position, assessment of position is critical for male mating success.

Species of dance flies (subfamily Empidinae) have elaborated on this basic pattern. Males of many species catch prey (usually smaller flies and other soft-bodied insects) and carry them in the swarm. They offer the prey to the nonhunting females as "nuptial gifts" to be fed upon during mating. A few species have reversed the trend of male-dominated swarms: instead, females form the aggregation, which prey-bearing males visit to selectively mate with the most desirable individuals (such female-dominated swarms are also known for some Phoridae). In some dance flies, the prey items themselves have changed, with males presenting already fed-upon prey, inanimate objects such as plant seeds, or even inedible bodily secretions. In these species, the giving of nuptial gifts apparently has become ritualized, losing all of its functional basis.

Conservation Biology of Diptera

Because of the perception of almost all Diptera as disease-carrying filth flies, there is little public sympathy or interest in their conservation. Also, most Diptera are extremely poorly known, and the study of many families is still contingent on the recognition and description of the many undescribed species.

An exception to these statements is the Syrphidae, a group that is popular among amateur collectors, especially in Europe. There, Red Lists of endangered species exist for many regions, including Britain and parts of the mainland. When species that are at the edge of their distribution are eliminated from consideration, it appears that most endangered syrphids are either saproxylic or associated with wetlands.

Saproxylic insects of all orders are considered to be among the most endangered insects in Europe. These are species that are obligately associated with rotting wood, a habitat that is largely absent from young, even-aged tree plantations or from older forests that are sanitized or managed by removal of dead trees and wood. Most of the saproxylic habitats are afforded by old-growth forests with adequate numbers of injured, bleeding, moribund, or dead trees available. Different species of insects are associated with different types of decay, including whether or not the trees are still standing. Other variables include whether the trees are large or small, whether they are exposed to light and low humidity or are shaded throughout the day, and how long the process of decay has proceeded. Rot holes (some of which contain water), sap runs, dead branches on otherwise healthy trees, and loosened bark are all microhabitats that have specialized insect (including Diptera) faunas. The saproxylic faunas of other regions have not been assessed, but as deforestation proceeds throughout the world, Diptera associated with this habitat will likely be threatened.

Wetlands have been greatly reduced in many areas of the world, in many instances for the express purpose of eliminating biting fly vectors of disease. The loss of such habitats, however, also eliminates populations of other aquatic Diptera that have important ecological roles in the environment.

Another group of Diptera whose conservation needs are relatively well known is the endangered fauna of Hawaii. There are several species of *Drosophila* that have been proposed for listing as endangered species.

Because of their poor public image, Diptera are usually not considered flagship species for conservation projects. In

the southwestern United States, however, an endangered species of mydid fly has been used to spearhead efforts to halt the final destruction of an endangered habitat in the Los Angeles area. The Delhi Sands Giant Flower-Loving Fly (*Rhaphiomidas terminatus abdominalis*) is the largest and most identifiable of a number of threatened taxa that live in this habitat, which is reduced to just a few acres in extent. The other subspecies of this taxon, *R. t. terminatus*, previously went extinct when its habitat in the coastal dunes near the Los Angeles International Airport was almost completely destroyed by urbanization. Other species of *Rhaphiomidas* are also considered endangered, as are other Diptera living in small, isolated, sandy habitats.

In general, the conservation status of Diptera on a world-wide scale is unknown. Undoubtedly many species are lost to deforestation, but only those in a few well-known groups (like syrphids) or in habitats that are of interest to some people (wetlands, sand dunes) have been studied. The situation is unlikely to change until we know much more about the systematics of flies.

Glossary

Brachypterous Having tegmina and wings shorter than the abdomen but overlapping or touching each other on the dorsum.

Cerci Paired, usually not segmented structures at the end of the abdomen, sometimes used by males during mating to grasp the female's abdomen.

Hemimetabolous Having incomplete metamorphosis, that is, showing gradual change from molt to molt, with externally developing wing pads, and lacking any larval and pupal stages.

Hypognathous Position of the head when the mouth is directed toward the ventral side of the body.

Macropterous Having wings that are fully developed, reaching or exceeding the end of the abdomen.

Micropterous Having wings that are greatly shortened, not overlapping or touching on the dorsum.

Prognathous Position of the head when the mouth opening is directed forward.

Spermatophore A membranous package containing sperm that is transferred from the male to the female during copulation.

Stridulatory apparatus An organ of sound production based on the mechanism of rubbing one part of the body against another.

Tegmina (singular: tegmen) Thickened forewings.

Overview of Orthoptera

Introduction

Orthoptera are hemimetabolous insects, with nymphs resembling adult forms in their general appearance but lacking fully developed wings and reproductive organs. Mouthparts of orthopterans are of the chewing/biting type (mandibulate). The head is hypognathous, rarely prognathous; the antennae are usually long and threadlike, consisting of fewer than 10 to several 100 segments. The part of the body immediately behind the head, or the pronotum, is usually large, often shieldlike, and in extreme cases covers a large part (many katydids) or the entire body of the insect (pygmy grasshoppers).

The front and middle legs are cursorial (i.e., adapted for walking); yet in some cases, the front pair of legs may be modified for digging (mole crickets, pygmy mole crickets, and false mole crickets), or both the front and middle pairs may be modified for grasping (predatory katydids). In some orthopterans (most katydids and crickets), the front legs have tibial auditory organs (the ear). The hind legs of most orthopterans are saltatorial (i.e., modified for leaping), with large, muscular femora and long, slender tibiae. Some grasshoppers can perform repeated leaps of 2.6 m without any obvious signs of fatigue. This is possible primarily because of the presence of a protein called resilin in their hind legs. Resilin has superb elastic properties, with 97% efficiency in returning stored energy. This allows for explosive release of energy that catapults the insect, a task impossible with muscle power alone. Certain groups of orthopterans, especially those leading a subterranean life, have lost their ability to jump and their hind legs resemble typical cursorial legs. In some grasshoppers and certain Ensifera, the inner surface of the hind femur is modified for sound production (stridulation).

The wings of orthopterans are either fully developed or reduced to various degrees. Wing polymorphism, or the occurrence of individuals with well-developed and reduced wings within the same species, is common. The forewings are somewhat thickened, forming leathery tegmina. In most katydids and crickets, parts of the tegmina are modified for stridulation. The hindwings, when present, are fanlike, hidden under the first pair in the resting position. Often the hindwings are longer than the tegmina and protrude behind their apices. Wing buds of nymphal stages are always positioned in such a way that the second pair of wings overlaps the first one, whereas in adult individuals of micropterous and brachypterous species, the first pair of wings always overlap the second pair, despite their nymphal appearance. The base of the abdomen in grasshoppers has lateral auditory organs known as abdominal tympana. Females of most orthopterans have a prominent ovipositor at the end of the abdomen, derived from the eighth and ninth abdominal segments. Katydids and crickets usually have a well-developed ovipositor – sword-, sickle-, or needle-shaped ovipositor, whereas females of grasshoppers and their relatives usually lack a long, external ovipositor.

The number of described species of Orthoptera is approximately 25–600. However, this number probably represents only a half or less than the actual number of species of Orthoptera present on the Earth today. Tropical regions of South America, Africa, and Asia still remain virtually unexplored in terms of their grasshopper and katydid fauna, and many thousands of species are expected to be described in the future. The Australian orthopteran fauna is the best studied of all tropical regions of the world, yet more than 1000 Australian species still remain to be formally described despite being already recognized as new to science.

Members of the order Orthoptera inhabit virtually all terrestrial habitats of the world, from rock crevices of the littoral

zone of the oceans, subterranean burrows, and caves, to tree-tops and peaks of the alpine zones of mountain ranges. Both deserts and grasslands as well as dense forests have rich and unique orthopteran faunas. There are few purely aquatic forms, but many are associated with marshes and other semiaquatic habitats. Orthopterans are important members of nearly all terrestrial ecosystems, both in the role of consumers and prey. Massive outbreaks of some species of grasshoppers (and less frequently katydids and crickets) can cause enormous losses for the food industry and forestry. Locusts (a vernacular name for certain grasshopper species that tend to produce large seasonal outbreaks, and not a taxonomic entity) have been a part of human history from the very beginning of our agricultural tradition. They still pose a great risk for agriculture in many parts of the world, although they pose less of a problem now than a few hundred years ago, thanks mostly to better understanding of their population dynamics and application of various chemical and biological control measures.

Sound Production

The single characteristic most frequently associated with grasshoppers and their relatives is their ability to produce sounds. Although less widespread than generally believed, this ability is nonetheless quite common in some groups of orthopterans. The role of sound production is threefold and similar in some respects to that of birdcalls: (1) attraction of mates, (2) territoriality, and (3) disbursement of release calls (alarm calls produced when seized by a predator). The calls of orthopterans are usually species specific and play a very important role in species recognition. The information in the call may be coded in the form of frequency modulation (the pitch of the call changes through time, a mechanism best known in birds), time modulation (the pitch of the call remains the same throughout its duration but its temporal pattern is unique to the species), or both modes combined.

The dominant mechanism of sound production in Orthoptera is stridulation, which involves rubbing one modified area of the body against another. Contrary to the popular belief, no orthopterans (or any insect for that matter) produce sound by rubbing their hind legs against each other. Katydids (Tettigoniidae) and crickets (Gryllidae) produce sound by rubbing a modified vein (the stridulatory vein) of one tegmen against a hardened edge of the second tegmen (the scraper). The stridulatory vein is equipped with a file-like row of teeth, the number of which varies from a few to a few hundred. In most katydids, the stridulatory area is situated at the base of the tegmina, except in brachypterous species where it covers their entire surface. In crickets, virtually the entire surface of the tegmina is modified for stridulation. As a rule, in katydids, the stridulatory file is situated on the left tegmen and the scraper on the right one, whereas in crickets, the situation is reversed. A membranous area at the base of the tegmen, the mirror, amplifies the sound. In addition, some katydids (e.g., *Thoracistus*) use their enlarged, shield-like pronotum as an additional sound amplifier. Crickets, lacking the enlarged pronotum, use other methods of sound amplification, such as singing from burrows, the shape and size of which is attuned

to boost certain frequencies (*Gryllotalpa*), or using the surface of a leaf for the same purpose (*Oecanthus*). The ability to stridulate is restricted almost exclusively to males, although in a few groups of katydids (Phaneropterinae and Ephippigerinae), females respond to the male's calls by stridulating as well. Their sound apparatus is not homologous to that of the males and is usually quite simple, lacking the sophisticated mechanism for sound amplification. In addition to tegminal sound apparatus, a few groups of katydids have developed other mechanisms of stridulation. For example, all members of the Australasian subfamily Phyllophorinae lack the typical wing stridulation and produce sound, instead, by rubbing their hind coxae against modified thoracic sterna. Mandibular sound production occurs in some members of Mecopodinae.

Grasshoppers use the same principle of stridulation, but instead of rubbing their tegmina against each other, these insects produce sound by rubbing the inner surface of the hind femur against one of the veins of the tegmen. In the slant-faced grasshoppers (Gomphocerinae), the inner surface of the femur possesses a file of small knobs, whereas the vein on the tegmen acts as the scraper. In band-winged grasshoppers (Oedipodinae), the vein has a row of pegs and the femur plays the role of the scraper. In addition to these two principal mechanisms, some grasshoppers stridulate by rubbing their hind legs against the sides of the abdomen (Pamphagidae) or by kicking their legs/feet against a modified area at the apex of the tegmen (*Stethophyma*). The males of South African bladder grasshoppers (Pneumoridae) produce sound by rubbing their hind legs against a greatly enlarged, balloon-like abdomen, and the sound produced in this way can be heard from a distance of at least 2 km. Australian false mole crickets (Cylindrachetidae) have a stridulatory file at the base of their maxillary palps, and some species of pygmy mole crickets (Tridactylidae) produce sound by rubbing a modified vein on the dorsal side of the tegmen against another vein at the base of the hindwing.

The sound frequencies produced by orthopterans during stridulation vary from a few kilohertz (most crickets and grasshoppers) to well above 100 kHz (some katydids). Crickets' calls are characterized by their tonal purity, with most energy of the call allocated within a narrow range of frequencies. Katydid calls vary from tonally pure (although often well above the human hearing range) to broad, noise-like signals. Grasshoppers produce mostly broad-spectrum, noise-like calls. Unlike many vertebrate calls, many orthopterans produce time-modulated rather than frequency-modulated signals. Crickets are a notable exception and most species produce melodious, bird-like, frequency-modulated chirps (although their calls are also time modulated.)

In addition to stridulation, some grasshoppers crepitate in flight. In this case, the sound is produced by hitting certain veins of the wings against other veins. This behavior is especially common among band-winged grasshoppers (Oedipodinae) and plays an important role in courtship and territorial displays.

A few members of normally acoustic orthopterans have lost their ability to produce airborne signals and instead have developed a number of substitute mechanisms of substrate-borne communication. Males of the oak katydids (*Meconema*)

lack the typical tegminal sound apparatus and instead produce sound by drumming with their hind legs against the bark of trees. Similar drumming behavior, although still accompanied by typical stridulation, is a component of the courtship behavior of the pitbull katydid (*Lirometopum*). The male crickets of the genus *Phaeophilacris* have lost their ability to stridulate and instead signal by rapidly flicking their tegmina back and forth while holding them in the vertical position. The near-field motion is detected by a female's cerci, rather than by her ears. Despite having a fully developed stridulatory apparatus, many neotropical members of the katydid subfamilies Pseudophyllinae and Conocephalinae spend little or no time stridulating, relying instead on substrate-borne tremulations. In this case, a male stands rigidly on a leaf or stem of a plant and violently shakes his entire body. The low-frequency waves are transmitted along the branches of the plant. The reason for this behavior is unclear, although a few hypotheses trying to explain it have been proposed. The most widely accepted one is the avoidance of predation by foliage-gleaning bats that are known to use insect sounds to locate their prey. Others include eluding satellite males (nonsinging males of the same species trying to intercept a female), avoidance of parasitoid flies, and helping females locate males on multibranched plants. Thanks to the rapid development of recording techniques in recent years, it is now known that many groups of orthopterans previously believed to be silent appear to employ a number of techniques of substrate communication.

Reproduction and Growth

The courtship and mating behavior of orthopterans provide some of the most complex and fascinating spectacles of the insect world. In addition to sound production, as discussed earlier, many species employ visual, tactile, and olfactory signals in their mating strategies. Visual communication is especially well developed in grasshoppers, where males often have bright, species-specific markings on different parts of their bodies, displayed in carefully choreographed sequences during courtship. Grasshoppers of the genus *Syrbula* are definite champions in this respect; and males of some species, in addition to calling, perform a dance consisting of 18 distinct movements. Visual signals employed by many diurnal grasshoppers include flight displays, where males flash their colorful hindwings (this is sometimes accompanied by crepitation), flagging with distinctly colored hind legs, and displays involving brightly colored, and often enlarged antennae. The courtship of katydids and crickets relies less on visual signals and more on sound and chemical cues, which are more appropriate for these mostly nocturnal animals. In both groups, males sometimes produce two different types of calls, a long-range advertisement call and a quieter, courtship song, performed only in the presence of a female. Females in some species may reply using either airborne signals or tremulation.

Chemical communication in Orthoptera is little studied, but there is evidence that at least some species employ it during courtship. Females of the New Zealand giant weta *Deinacrida rugosa* produce a musky substance that males use to locate females, whereas males of camel crickets of the genus *Ceuthophilus* possess thoracic glands that may also play a role in

courtship. Field crickets *Teleogryllus commodus* use pheromones covering the female antennae to initiate courtship. Some other crickets use airborne pheromones in locating members of the opposite sex.

Copulation in orthopterans involves transfer of a sperm sac (spermatophore), which in some groups is accompanied by a large packet of nutritious proteins, the spermatophylax. Males of some orthopterans also allow females to feed on parts of their own bodies during copulation. Males of haglids (*Cyphoderris*) have their hindwings modified into thick, fleshy lobes, the sole purpose of which is to be eaten by the female during copulation. Females of tree crickets (*Oecanthus*) feed on males' thoracic glands during copulation; and in some crickets of the subfamily Nemobiinae, the females feed on enlarged spines on males' hind tibia. New evidence suggests that nuptial feeding from special glands on the male's body is also present in some katydids. Males of other orthopterans, lacking such tasty incentives, must rely on their strong grasp or modified cerci at the end of the abdomen to hold the female during copulation.

Oviposition takes place in a variety of substrates, such as soil, plant tissues, or rock crevices. In some cases, eggs are protected from desiccation by a foamy mass produced by the female. Nymphs usually hatch within a few weeks or months, but sometimes the eggs undergo a year-long, or longer, diapause. Few orthopterans display any kind of parental behavior, although some crickets (*Anurogryllus*) lay eggs in burrows guarded by the female. Female mole crickets (*Gryllotalpa*) not only lay eggs in special egg chambers underground but also actively care for the eggs by licking and removing fungal spores from their surfaces. The hatchlings stay with their mother for a few weeks before dispersing.

Food and Feeding

Orthopterans are extremely diverse in their food preferences and feeding techniques. Virtually all Caelifera (grasshoppers and their allies) are strictly herbivorous, very rarely engaging in cannibalistic behavior, and doing so only under crowded conditions. Most grasshopper species seem to be polyphagous (feeding on a wide variety of plant species), but some are oligophagous (feeding on a narrow spectrum of plant species) or monophagous (feeding on only one species of plants). The last are often associated with toxic, alkaloid-rich plant species, and these substances make the insect themselves inedible to many potential predators. Pygmy grasshoppers (Tetrigidae) are some of the few insects that feed on mosses and lichens.

Ensifera (katydids, crickets, and their relatives) range from herbivorous to omnivorous to strictly predaceous. Some katydids specialize on rather unusual food sources. Members of the Australian genus *Zaprochilus* feed exclusively on pollen and nectar of flowers. However, most katydids feed on a wide range of organic material. For example, the Central American Rhinoceros katydid (*Copiphora rhinoceros*) is known to feed on flowers, fruits, hard seeds, caterpillars, other katydids, snails, frog eggs, and even small lizards. Strictly predaceous katydids employ both the "sit-and-wait" strategy (Saginae) or actively forage and hunt living insects (Listroselidinae). Some raspy crickets (Gryllacrididae) also actively search for insect prey by rapidly running along branches and grasping any sitting insect

they encounter. Crickets and cave crickets tend to be generalists in their dietary preferences, but rarely exhibit tendencies to feed on live prey. Some mole crickets have a behavior unique among orthopterans, and insects in general, of gathering and storing germinating seeds in circular chambers below the ground for later consumption.

Phylogeny and Taxonomy

Despite a long history of taxonomic research on orthopteroid insects and despite their economic importance, there is still little agreement as to the taxonomic position of many groups of the Orthoptera, and large portions of the current classification system is still based on nineteenth-century works. Older classifications also included groups, such as cockroaches (Blattodea), praying mantises (Mantodea), walking sticks (Phasmida), and earwigs (Dermaptera), in this order, each of which is now considered a separate, albeit closely related order. For the purpose of this review, the classification system proposed by Eades et al. (2011) has been adopted. This system divides the order Orthoptera into two suborders: Ensifera, with superfamilies Tettigoniioidea (katydids), Hagloidea (grigs), Grylloidea (crickets), Schizodactyloidea (splay-footed crickets), Stenopelmatoidea (Jerusalem crickets and relatives), and Rhaphidophoroidea (camel crickets); and Caelifera, with superfamilies Eumastacoidea (monkey grasshoppers), Pneumoroidea (bladder grasshoppers), Tanaoceroidea (desert long-horned grasshoppers), Acridoidea (grasshoppers and locusts), Pyrgomorphoidea (gaudy grasshoppers), Trigonopterygoidea (leaf grasshoppers), Tetrigoidea (pygmy grasshoppers), and Tridactyloidea (pygmy mole crickets and relatives). The following differences generally allow Ensifera and Caelifera to be distinguished (note that there are numerous exceptions):

<i>Ensifera (katydids, crickets, and relatives)</i>	<i>Caelifera (grasshoppers and relatives)</i>
Antennae long and thin, with more than 30 segments	Antennae short, with less than 30 segments
Anterior tibiae usually with tympanal organs	Anterior tibiae without tympanal organs
Ovipositor long, sword- or needlelike	Ovipositor very short
Sound produced by tegminal stridulation	Sound produced by rubbing hind legs against tegmina

The monumental task of describing all living species of Orthoptera is far from complete. As the exploration of tropical regions of the world progresses, more and more species waiting to be formally described accumulate in museum collections worldwide. Unfortunately, at the same time, the number of specialists capable of such work is dwindling rapidly.

Paleontology

The Orthoptera is an old group, dating back to the Carboniferous period. Along with Titanoptera and Phasmida (Phasmatoptera), they represent the superorder Orthopterodea.

Both Titanoptera and Phasmida branched off of the main stock of Orthopterodea in the early Permian period. Titanoptera disappeared at the end of the Triassic period, whereas Phasmida (walking sticks and their relatives) and Orthoptera still flourish today. The two main lineages of Orthoptera, Ensifera and Caelifera, probably separated in the late Carboniferous period. Most modern families of Ensifera appeared between the early Jurassic and the early Triassic periods. The oldest, still extant family of Ensifera, the Prophalangopsidae, appeared in the early Jurassic period. The oldest family of Caelifera, the Eumastacidae, appeared in the middle Jurassic period, followed by the Tetrigidae and the Tridactylidae at the beginning of the Cretaceous period.

Tettigoniioidea (Katydids)

Introduction

The superfamily Tettigoniioidea includes only one family, the Tettigoniidae (katydids or bush crickets), although some authors have elevated several subfamilies of katydids to the status of separate families (Figure 1). It is the second largest group of Orthoptera (grasshoppers being more species rich), with more than 6800 described species assigned to nearly 1200 genera and 20 subfamilies. Tettigoniioidea are characterized by the presence of well-developed tegminal stridulatory apparatus in the males; long, thread-like antennae, usually longer than the body; four-segmented tarsi; short, nonarticulated cerci in the males; and a large external ovipositor in the females. The wings, when present, are usually held in a roof-like fashion over the abdomen. Virtually all members of the superfamily have bilateral tympanal organs on the front tibia as well as an additional acoustic trachea on the thorax behind the pronotum.

The Tettigoniioidea are distributed throughout the world, but like most other orthopterans, they show their greatest diversity in the tropical and subtropical regions. Although many groups of katydids are quite diverse in temperate regions of the world, they are less common in areas with long, cold winters. A large proportion of the Tettigoniioidea are arboreal but many also inhabit grasslands, savannas, deserts, or rocky

Figure 1 Tettigoniioidea: Katydid *Celidophylla albimacula* from Costa Rica.

mountain tops. Most species are nocturnal or crepuscular, although several major groups consist almost exclusively of diurnal species.

Major Lineages

Tettigoniidae (Katydids or Bush Crickets)

Katydids are a large and diverse group of orthopterans, elevated by some authors to the rank of a superfamily with numerous families. More than 6900 species have been described, placed in nearly 1200 genera and 20 subfamilies. Most katydids are medium- or large-sized insects. The largest katydid, *Siliquofera grandis*, from New Guinea, has a wingspan of more than 250 mm. On the other hand, members of the Australian subfamily Microtettigoniinae have a wingspan of less than 10 mm.

Males of almost all species have a well-developed stridulatory apparatus at the base of the tegmina. The exceptions are the subfamilies Phyllophorinae, Phasmodinae, and some members of Meconematinae and Mecopodinae. Males of the Australasian subfamily Phyllophorinae, despite having fully developed wings, lack the stridulatory apparatus and instead produce sound by rubbing their hind coxa against specially modified thoracic sterna. Australian Phasmodinae lack wings altogether and are presumably totally silent. This is also the only subfamily of katydids having greatly reduced tympanal tibial structures ("the ear") and lacking the thoracic auditory spiracle. All katydids have long, thin antennae, often longer than the body, in extreme cases exceeding its length three to four times. The head of katydids is hypognathous (mouth directed down), rarely prognathous (mouth directed forward) (Phasmodinae and Zaprochilinae); and sometimes bears distinct, cuticular, horn-like processes between the antennae. Their function is uncertain, but is likely related to the fact that many predators (especially bats and birds) tend to seize their katydid victims by the head. The pronotum is enlarged, saddle shaped, and in some forms greatly expanded, covering part of the wings and the abdomen. In the male, the enlarged pronotum often acts as a call amplifier. Curiously, the group with a particularly enormous, box-like pronotum, the Phyllophorinae, lacks the ability to produce sounds with their wings. The pronotum is also sometimes armed with sharp spines and processes. The wings of katydids can be fully developed or reduced to a varying extent, in some lineages (Tettigoniinae) showing significant intraspecific polymorphism in the degree of their development. The tegmina are sometimes reduced to scale-like structures, the only function of which is sound production. Hind wings in such taxa are either totally missing or are greatly reduced. Many katydids use their wings to enhance their remarkable mimicry of leaves, twigs, or bark to a degree that can fool professional biologists. Members of the neotropical tribe Pterochrozini are particularly convincing mimics of both live and dead leaves, perfectly imitating the look and feel of leaves, including simulated traces of herbivory, with fake lichens and mosses "growing" on them. A few katydids are Batesian mimics of wasps.

The legs of katydids are usually long and slender. Predaceous species frequently have rows of long spines along the ventral edges of the front and middle legs, using them for

grasping and holding prey. In some Listroscelidinae, the spines are particularly long, forming a kind of net, used for scooping small flies and other insect prey. The hind legs are saltatorial, except for the members of some groups living in burrows or under rocks (Hetrodinae and Bradyporinae). The abdomen of males has a pair of cerci, in some groups modified to grasp the end of female's abdomen during mating. The ovipositor of females is usually long and sickle or sable shaped. The reduction of the ovipositor to short processes appears independently in ground-dwelling forms (Hetrodinae) and some arboreal ones (Phaneropterinae), apparently related to the fact that the eggs are laid on the surface of the soil or leaves, rather than inserted into them, as most katydids do.

The significant male investment in offspring is one of the characteristics of katydids that attracts many researchers to study their behavior and evolution. During copulation, males of many katydids produce a large, protein-rich spermatophylax, which is eaten by the female after copulation. The size of the spermatophylax can approach 60% of the male's body mass, making it an extremely costly and significant contribution to egg production. This causes the males of many species to be quite choosy in selecting their mating partners; and under certain circumstances, the females may compete for males, a role reversal remarkably rare in the animal world.

The geographic distribution of katydids reveals several large centers of endemism, the largest being Australia, where 5 of the 13 subfamilies known from the continent are unique to it. The neotropics have the highest number of described species (approximately 1800) but no endemic subfamilies, followed by Eurasia (approximately 1350 species), the Indo-Malaysian region (approximately 1150), and Africa (approximately 850 species and 2 endemic subfamilies). However, these numbers are very likely to be multiplied in the future if taxonomic work in these regions is intensified.

Major Subfamilies

Bradyporinae This is likely the most basal subfamily of katydids and is characterized by having a large, stout body, greatly reduced wings, and the tarsus with a metatarsal pulvillus. Members of this family are restricted in their distribution to southwestern Palearctic. Often grouped with several other subfamilies (Hetrodinae and Ephippigerinae), they nonetheless appear to be a separate clade of their own. Approximately, only 50 species have been described. All species of the subfamily are dark colored, often black, and resemble giant crickets rather than typical, graceful katydids. Most live on the ground or low vegetation. Some species are known to produce defensive autohemorrhage and squirt their hemolymph from orifices on their body if the insect is seized by a predator.

Phaneropterinae This is the largest subfamily of Tettigoniidae, with more than 2200 species described from all continents of the world (other than the polar regions). Members of this subfamily are medium- to large-sized insects, usually green and leaf-like katydids, characterized by a lack of lateral grooves on the tarsi, and rather primitive venation of the wings. Wing reduction is widespread in several lineages of the subfamily but the stridulatory apparatus is always present. Female stridulation is known in a few genera. Virtually

all species are phytophagous, although opportunistic cannibalism has been observed in a few species. Many species are exclusively arboreal. Eggs are laid in the soil, plant tissues, or on the surfaces of leaves and bark. Immature stages of many species mimic ants, tiger beetles, and even spiders, whereas adults of the same species usually mimic leaves or blades of grass. Several South American genera are superb mimics of pompilid wasps.

Acridoxeninae This is a small, aberrant subfamily of large Central African katydids, with only one species, *Acridoxena hewaniana*. Its relationship to other katydids is uncertain as it displays a mixture of very advanced and very primitive characteristics. The most interesting feature of *Acridoxena* is its astonishing mimicry of a dried, spiny plant. All parts of the body look like shriveled, twisted, dry leaves or twigs. Nothing is known of its biology or behavior.

Ephippigerinae This is a small Palearctic subfamily, with approximately 140 described species. All species have greatly reduced, scale-like wings, usually hidden under an enlarged, saddle-shaped pronotum. Females of many species stridulate and certain species have long been model organisms for studies on acoustic communication and courtship in insects. Some species occasionally cause minor agricultural damage.

Pseudophyllinae This is the second largest subfamily of Tettigoniidae, with approximately 1100 described species, distributed in tropical and subtropical regions of the globe. A notable exception is the true katydid (*Pterophylla camellifolia*) of eastern USA, which is both the northernmost member of the subfamily and the source of the name "katydid." Its characteristic, loud call resembles (although some listeners disagree) the syllables "ka-ty-did." Most pseudophylline katydids are found in the tropical areas of South America and Southeast Asia. Many are spectacular mimics of leaves (tribes Pterochrozini and Pseudophyllini) and bark (tribes Plemnini and Cymatomerini). Secondary loss of stridulation and widespread presence of tremulation is characteristic of many neotropical members of the subfamily. On the other hand, Old World members of the subfamily belong to the loudest night singers of tropical forests. This disparity in their acoustic behavior has been explained by different hunting strategies of insectivorous bats in the New and the Old World, which in turn shaped different defensive strategies among acoustic insects. Nearly all species of the Pseudophyllinae are arboreal or at least associated with tall vegetation. A notable exception is the genus *Callimenellus*, which is known to inhabit marine littoral rock crevices in Hong Kong. All species seem to be phytophagous although opportunistic insectivory has been observed in a few Central American species. Virtually all species are nocturnal.

Tettigoniinae It is a large subfamily, with nearly 1000 described species. Most of the species of this subfamily occur in the temperate regions of the world, and only a handful of species are present in the tropics. Tettigoniinae achieved the greatest diversity in the regions of Europe, western North America, South Africa, and Australia characterized by the Mediterranean type of vegetation. Many species have a large,

shield-like pronotum, hence the common name "shield-backed katydids." Females always have a long, sword-like ovipositor and lay eggs in soil or the stems of herbaceous plants. Males stridulate loudly and many species are active during the day. A few species of shield-backed katydids are agricultural pests, the best known being the Mormon cricket (*Anabrus simplex*) of western USA. However, some species in China and Japan have been kept as pets for hundreds of years, and their pleasing calls have made a remarkable impact on the poetry and other arts of these countries.

Conocephalinae The conehead katydids are a large subfamily of Tettigoniidae, with more than 1100 described species worldwide. Many are characterized by a prominent fastigium of the vertex, forming a characteristic "horn" on the head. The diet of many of these katydids is restricted to grasses and their seeds, although quite a few species are predaceous. The conehead katydids are quite common in temperate regions of North America and Europe, although they reach their greatest diversity in the tropical areas of South America. Some species of Conocephalinae may become agricultural pests and a few have been known to form large, locust-like swarms (*Ruspolia*). Male investment in offspring can be significant in some neotropical conehead katydids, and an elaborate courtship behavior is common in such species.

Phasmodinae and Zaprochilinae These two, closely related subfamilies are restricted to Australia. Phasmodinae contains only one genus, *Phasmodes*, with three species restricted in their distribution to Western Australia. These insects are a good example of convergent evolution, resembling walking sticks (Phasmida) to an extraordinary degree. Both sexes are completely wingless, and females lack tibial tympana as well as thoracic auditory spiracles. The entire body is extremely elongate and thin, and the head is prognathous. A simple way of telling these insects apart from walking sticks is looking at the proportions of thoracic segments. In real walking sticks, the prothorax is extremely elongated, whereas in *Phasmodes*, it is the mesothorax that has such modification. These interesting katydids feed on both leaves and flowers of the heath habitats.

Zaprochilinae They have similarly elongated bodies and prognathous head, but all species have wings. They are strongly reduced in the genus *Kawanaphila*, but fully developed in the remaining three genera of the subfamily. Males of all 28 described species produce short, ultrasonic calls. Several species of the subfamily have been extensively studied with regard to the parental investment of males, which is significant and may lead to courtship role reversal. All members of the subfamily feed primarily on pollen and nectar, and they play some role in pollination of the flowers on which they feed.

In addition to the above-described subfamilies, the family Tettigoniidae also includes the following subfamilies: Austrosaginae, Hetrodinae, Lipotactinae, Listrosclidinae, Meconematinae, Mecopodinae, Microtettigoniinae, Phyllophorinae, Saginae, Hexacentrinae, and Tympanophorinae.

Figure 2 Hagloidea: Grig *Cyphoderris strepitans* from Wyoming, USA.

Hagloidea (Grigs or Hump-Winged Crickets)

This ancient superfamily, dating back to the early Jurassic period, is represented by only eight extant species placed in a single family Prophalangopsidae (Figure 2). They are characterized by a rather primitive stridulatory apparatus lacking a proper mirror, head with antennae inserted near the lower margin of the eyes, and the metatarsus with a well-developed pulvillus. The largest of these Mesozoic relics is *Prophalangopsis obscura*, with the wingspan of more than 100 mm, found on the Tibetan Plateau. The remaining eight species belong to four genera distributed in western North America (*Cyphoderris*) and northeastern Asia (*Paracyphoderris*, *Aboilomimus*, and *Tarragoilus*). The biology of *Cyphoderris* is quite well known and some species of the genus are often used in studies on mating behavior and parental investment in offspring. The male's stridulatory apparatus is almost perfectly symmetrical, that is, males have fully functional files and scrapers on both tegmina and can produce sound with either the left or right tegmen (hence the name "ambidextrous crickets," is sometimes applied to these insects). The hindwings are reduced to fleshy lobes, which are devoured by the female during copulation. Males who had already mated once and are missing these courtship "snacks" must resort to other methods of holding the female's attention and instead use the "gin trap," a complex system of cuticular modifications whose role is to hold the female's abdomen firmly in place during copulation. These insects are also unique in their ability for being active, and even call during winter, from snow-covered bushes, when the temperature oscillates at approximately 0 °C.

Grylloidea (Crickets and Mole Crickets)

Introduction

The superfamily Grylloidea includes nearly 5300 described species placed in more than 670 genera and four families (Figure 3). Crickets are small- to medium-sized insects, the smallest species being only approximately 1.5 mm long (Myrmecophilidae) and the largest approximately 60 mm (Gryllotalpidae). The family is cosmopolitan in its distribution and some species occur even within the polar regions,

Figure 3 Grylloidea: Field cricket *Gryllus veletis* from northeastern USA.

albeit usually only in association with human dwellings. Most members of the subfamily are brown or black, very rarely green. The antennae are usually thin, threadlike, and longer than the body (with the exception of certain burrowing forms). The head is usually large and almost globular, although it may be somewhat elongate and prognathous in some lineages (Oecanthinae and Gryllotalpidae). The pronotum is usually quadrate, rarely produced backward as to cover the wings (a condition common in katydids). The tarsi of the legs are three segmented (superficially four segmented in Oecanthinae), and the front legs are sometimes strongly modified for digging. The front tibia typically have well-developed bilateral tympanal organs. Hind legs are usually saltatorial but are occasionally short and not adapted for leaping. Wings are usually present but may be reduced to various degrees or totally absent (Myrmecophilidae). The tegmina are held flat on the dorsum and their anterior (lateral, in the resting position) margins are bent downward at an angle, forming a box-like structure. The stridulatory apparatus of males is well developed in most groups, although it may be absent even in some fully winged taxa (some Pentacentrinae, Trigonidiinae, and Eneopterinae). The left and right tegmina of males have similar venation, but stridulation is performed virtually always with the right tegmen rather than with the left tegmen. The hindwings, when folded, often project far beyond the tegmina. Many taxa lack the hindwings and wing polymorphism is common. Male cerci are usually long, flexible, often superficially annulated, and never grasping. The ovipositor is usually long and needlelike, although it may be reduced or even absent in some crickets (Gryllotalpidae). Most species of crickets are nocturnal or crepuscular. They occur in almost all terrestrial habitats, from treetops to underground burrows, and many species are associated with aquatic and semiaquatic environments (such forms are usually very good swimmers). The great majority of crickets are opportunistic feeders and few seem to be exclusively predaceous.

Major Lineages

Gryllotalpidae (Mole Crickets)

This interesting family, which includes six genera and more than 100 described species of usually large, robust crickets, are

distributed worldwide. All species of the family spend their lives in underground tunnels, excavated with their extremely modified, shovel-like front legs. The head is prognathous and somewhat elongated, and so is the pronotum. The antennae are short and somewhat thickened, an apparent adaptation for their subterranean lifestyle. The wings are usually fully developed, rarely absent. The stridulatory apparatus of males is simple, lacking the mirror. The females' tegminal venation resembles that of the males, but lacks proper stridulatory organs. Cerci in both sexes are long and flexible, acting as an extra pair of antennae while the insects are moving backward in their underground corridors. Females lack an external ovipositor.

Mole crickets emerge from their tunnels only during courtship, although calling takes place underground. To broadcast their signals as far as possible, males build Y-shaped tunnels, the length and diameter of which are perfectly suited to amplify the dominant frequencies of their call. Females stridulate as well, but their call seems to have a territorial rather than a courtship role. Eggs are often laid in special brooding chambers and actively cared for by the female. Newly hatched nymphs stay in the chamber for a few weeks, feeding on humus and tender rootlets protruding into the burrow.

Several species of mole crickets are serious crop pests, not only because they feed on roots of plants but also because they damage entire root systems while digging tunnels. A species of *Gryllotalpa* recently introduced accidentally to Australia has quickly become one of the major threats to the Australian golfing industry by damaging carefully manicured putting greens.

Gryllidae (True Crickets and Tree Crickets)

The family Gryllidae is the largest lineage of the superfamily, with nearly 4700 species, assigned to nearly 600 genera in 21 subfamilies (there are several alternative systems of classification of crickets, and the number and status of higher categories varies among different authors). The body size of true crickets ranges from small (less than 5 mm) to large (approximately 50 mm). Most members of the family are rather stout insects, with short, thick legs. Phalangopsinae are a notable exception, having extremely long and slender legs and other appendages, making them resemble large spiders rather than typical crickets. Delicate bodies with slender legs also characterize most tree crickets (Oecanthinae). The head is generally globular, except in tree crickets, which have an elongated, prognathous head. The pronotum is generally quadrate. The wings and stridulatory apparatus may be fully developed, reduced, or totally absent. The fully winged forms often lack the stridulatory apparatus, whereas forms with greatly reduced tegmina can have a fully developed stridulatory apparatus. Species with well-developed stridulatory apparatus usually produce melodious, frequency- and time-modulated calls, and many species have been kept as singing pets in Asia and Europe for many centuries. Rarely, the call is short and clicklike (*Eneoptera*). Courtship behavior is often complex and involves acoustic, tactile, and olfactory signals. The courtship song, produced only in the close proximity of the female, is quieter and of a different structure than the advertisement call. It is usually produced by rubbing only a

part of the stridulatory file against the scraper. Some spider crickets (Phalangopsinae) additionally drum with their legs. During copulation, males produce spermatophores, which in some species contain a large spermatophylax. Males of some species allow the female to feed on different parts of their bodies. Males of tree crickets have thoracic glands, which the female licks during copulation, and females of some pygmy field crickets (Nemobiinae) feed on males tibial spines during copulation.

The ovipositor in true crickets is usually long, needlelike, sometimes laterally flattened, and swordlike (Trigonidiinae) or reduced (*Brachytrupes*). Opposition takes place in soil or plant tissues. Maternal care is rare but sometimes quite well developed. Females of *Anurogryllus muticus* excavate extensive subterranean burrows as a nursery for their eggs, which are aggressively protected against all intruders. Newly hatched nymphs stay with their mother, who feeds them with unfertilized eggs, produced by her for the sole purpose of feeding her nymphs.

Major Subfamilies

Gryllinae This subfamily includes the true crickets, placed in more than 1100 species and more than 100 genera. They are distributed worldwide, and a few species closely associated with human habitats are virtually cosmopolitan. Morphologically, Gryllinae are rather uniform, having stocky bodies, with a globular head and thick legs. Most have well-developed wings and a stridulatory apparatus. True crickets are some of the first singing insects to be heard in the spring in the temperate areas of Europe and North America, as they often overwinter as late-instar nymphs and mature as soon as the temperature allows them to become active. North America has a particularly interesting fauna of true crickets, with several complexes of morphologically nearly identical, so-called "cryptic species." Some of the species appear to be chronospecies, that is, very closely related species that avoid hybridization by being sexually mature during different times of the year.

Most true crickets are ground dwellers and many are territorial, vigorously defending their burrows. In some species, a certain percentage of the males (satellite males) consistently exhibit a kind of sexual parasitism by intercepting females attracted to the call of another male. Several species form large swarms, and some (e.g., *Gryllus bimaculatus* in Africa) can become serious agricultural pests. The house cricket (*Acheta domesticus*) is a cosmopolitan insect associated with human dwellings and when occurring in large numbers can cause damage to stored food and other material.

Brachytrupinae This subfamily, often treated as a subset of the true crickets, includes about 20 genera and more than 220 species distributed mostly in the tropical and subtropical regions of the Old World, with relatively few species in the New World. The wings in some species are greatly reduced or absent, and the female's ovipositor is reduced. Some of these crickets are very large and produce calls of an intensity directly proportional to their size. Some species are gregarious and live in small underground colonies consisting of adults and nymphs of different ages. Some species of the

subfamily exhibit extraordinary maternal care for their eggs and nymphs.

Phalangopsinae The spider crickets are characterized by having a rather robust body supported, in most cases, by very long, thin legs. The antennae and palps in such forms are also extremely long and slender. Wings are frequently reduced or absent, and some winged species lack the stridulatory apparatus in the male. On the other hand, some species are loud singers, with a pleasing call, and males of several Asian species are greatly prized for their songs and are kept in special little cages as pets. The subfamily includes about 380 species in nearly 100 genera, achieving the greatest diversity in the tropics of Central and South America. Many species inhabit caves and rock crevices as well as spaces between buttress roots of trees in tropical forests. Others prefer tree trunks, leaf litter, and decaying wood.

Oecanthinae The tree crickets are rather unusual members of the family Gryllidae, having a somewhat elongated, prognathous head and a rather long pronotum. The wings can be either fully developed or completely absent. Winged forms have a very well-developed stridulatory apparatus, capable of producing loud, pure sounds. Males of the genus *Oecanthus* enhance the range of their call by positioning themselves in a hole chewed out in a leaf, with their tegmina aligned during singing with the surface of the leaf. By doing this, they significantly increase the area from which the sound radiates, using the same principle on which speakers in radios and other musical appliances are built. Thanks to this technique, these small insects are capable of becoming the dominant singers in many environments.

Females of tree crickets lay eggs in the stems of plants, and by doing so may damage young trees in nurseries and orchards, thus becoming pests. On the other hand, many species feed on aphids, thus balancing the negative effect of their reproductive behavior.

Mogoplistidae (Scaly Crickets)

Scaly crickets are small, rarely exceeding 15 mm in length. Their name is derived from the fact that their entire body is covered with minute scales, reminiscent of the scales on the wings of butterflies and moths. Similar to these insects, the scales on the body of scaly crickets often form beautiful color patterns. However, unlike butterfly wings, the wings of scaly crickets are not covered with scales and are strongly reduced, often entirely concealed under a somewhat elongated pronotum. About 370 species have been described, placed in 30 genera. They are distributed worldwide, but Australia and the Indo-Malaysian region seem to have the largest share of known species.

Myrmecophilidae (Ant-Loving Crickets)

This small family seems to be closely related to Mogoplistidae and probably does not deserve the status of a separate family. Only about 10 genera and fewer than 70 species are known, and all of these are closely associated with colonies of social insects, mostly ants, and less frequently termites. All species are minute, sometimes less than 1.5 mm, with an oval,

wingless body and a small head with greatly reduced eyes. The hind femora are short and enormously enlarged.

Ant-loving crickets seem unable to live without a close association with ants or termites. Some species have a wide range of host species, whereas others are restricted to only one host species. The nature of this association is unclear. At least one myrmecophilous species, *Myrmecophila manni* from North America, appears to be able to mimic ant behavior to an extent that allows it to be fed by workers of its host, *Formica obscuripes*. Another species, *M. oregonensis*, feeds on residues of the substance that lubricates ants' bodies, left on the walls of passageways. A few species of these crickets appear to be parthenogenetic. Their eggs are relatively large and their embryonic development is long, sometimes lasting over a year.

Schizodactyloidea (Splay-footed Crickets)

The unusual superfamily Schizodactyloidea, which includes the single family Schizodactylidae, is unique in the peculiar modifications of the hind tarsi, which bear distinctive lobe-like processes that help the insects move on soft, sandy substrates. Species of the South African genus *Comicus* (Figure 4) are entirely wingless, whereas those of the southern Palearctic genus *Schizodactylus* have fully or partially developed wings. The Indian *S. monstrosus* has particularly long hindwings, which are coiled into tight, vertical spirals, a feature unique among all insects. All species of splay-footed crickets are very agile and feed on a variety of insects. A recently discovered fossil of splay-footed cricket indicates that forms remarkably similar to modern species were already present in Early Cretaceous period (approximately 108 million years ago.)

Stenopelmatoidea (Camel Crickets, Jerusalem Crickets, and Raspy Crickets)

Introduction

The taxonomy and phylogeny of this group of the Orthoptera seems to be in a greater disarray than that of any other lineage of the order. Many different names have been applied to this group of insects, and frequently various subgroups have been

Figure 4 Schizodactyloidea: Splay-footed cricket *Comicus capensis* from Namibia.

elevated to the levels of superfamilies or even infraorders. The superfamily Stenopelmatoidea includes about 980 species and more than 140 genera assigned to four families: Anostostomatidae (wetas), Cooloolidae (Cooloola monsters), Stenopelmatidae (Jerusalem crickets), and Gryllacrididae (raspy crickets) (Figure 3). Members of this superfamily are characterized by the lack of the tegminal stridulatory apparatus even in fully winged species. Tegmina, if present, are soft and characteristically curved around the abdomen. The head is usually large and bullet-like, and some forms have greatly enlarged mandibles. The antennae tend to be very long and threadlike, but in some subterranean forms (Cooloolidae), it may be strongly shortened. Tibial auditory structures are usually absent, and the thoracic auditory spiracle is small and simple. Acoustic communication in this group is not as common as in other orthopterans and is restricted to femoral stridulation (Gryllacrididae) and abdominal drumming (Stenopelmatidae). Body size varies from approximately 10–100 mm, and some species of New Zealand wetas are considered the heaviest insects in the world, reaching the weight of 70 g – nearly three times as much as an average house mouse. Coloration of species of Stenopelmatoidea is often drab, usually brown, black, or yellow, but never green.

The distribution of the superfamily is worldwide, with the exception of the Cooloola monsters, which are known only from northeastern Australia. Nearly all species of Stenopelmatoidea are nocturnal or crepuscular. Their habitats include treetops in tropical forests, savannas, and deserts, but a great proportion of species dwells in caves or underground burrows.

Major Lineages

Anostostomatidae (Wetas)

Approximately, 200 species placed in nearly 40 genera belong to this family. The body of these insects is usually fairly large and bulky, and New Zealand wetas are among the largest living insects (*Deinacrida heteracantha* reaches the weight of 70 g). The head is large and globular, with relatively short antennae. In some species, the powerful hind legs can serve as a weapon, and these species are capable of delivering strong and painful kicks. Wetas are generally wingless, but some neotropical species (*Anabropsis*) may have fully developed

wings (Figure 5). Tree wetas (*Hemideina*) exhibit complex social behavior, where males maintain harems of females in their refuges in holes and cracks in trees. Other males frequently try to take over the harems, and fights involving head-on clashing and gaping of their jaws are quite common among males. New Zealand and South African wetas often display a strong enlargement of the male mandibles, whereas males of South African *Henicus pattersoni* carry long, sharp “tusks” below their eyes. These structures are used primarily in combat with other males and territorial displays; but some species, such as the South African Parktown Prawn (*Labidonasidus vittatus*), use them for digging deep burrows. Some North American species (*Cnemotettix*) produce silk with their mouthparts, which is used to line their burrows in coastal sand dunes.

Cooloolidae (Cooloola Monsters)

Some of the most peculiar insects belong to this small family, consisting of only one genus and four species. They are restricted in their distribution to central and northern Queensland in Australia and were discovered only in 1980. Their appearance is so unusual that the first specimens ever collected were suspected of being fabricated as an entomological joke. The body of Cooloola monsters is so bulky that these insects, and especially the females, are almost incapable of walking on the surface of the ground. They spend their entire lives underground, digging through sand with their extremely thick and powerful legs. They are virtually blind and their short antennae consist of only nine segments. Their mandibles are elongate and sharp, and the maxillae (the second part of mouthparts) bear two dagger-like processes, which probably act as piercing organs, a situation absolutely unique within Orthoptera. The wings are vestigial in males and usually completely absent in females. The internal anatomy of these insects is also unusual in the fact that the foregut extends backward into the posterior part of the abdomen.

Little is known about biology of Cooloola monsters. They appear to “sand swim” through sand and do not construct burrows. They feed probably on body fluids of other subterranean animals.

Stenopelmatidae (Jerusalem Crickets)

This family includes about 40 described species, placed in 7 genera. They are known primarily from North and South America, South Africa, and southeast Asia. The legs are thick, powerful, and frequently well adapted for digging. Wings in Jerusalem crickets are usually absent and are rarely developed well enough for the insects to be able to fly. They do not have stridulatory organs on the tegmina, but many species communicate with elaborate percussive signals produced by drumming their abdomen against the substratum. The courtship behavior of Jerusalem crickets is an elaborate spectacle, involving a synchronized and precise positioning of the partners. If the female does not recognize the male as an acceptable partner, she devours him, thus preventing copulation. If the male is found to be acceptable, she allows him to mate and deliver to her a large spermatophore, and she attempts to eat him only afterward. This behavior may account for the rarity of male specimens of Jerusalem crickets in entomological collections. Most species of Stenopelmatidae

Figure 5 Stenopelmatoidea: *Anabropsis marmoratus* from Costa Rica.

spend their lives on or close to the ground or underground. Species of the genus *Oryctopus* from India include wingless, robust, and entirely subterranean forms that closely resemble Australian Cooloola monsters; whether the resemblance is the result of convergence due to a similar lifestyle or these two lineages are closely related is still unclear. Many species are predaceous, but most seem to be opportunistic generalists. Jerusalem crickets have been reported to cause minor injuries to crops by gnawing on roots and parts of the plants close to the ground.

Gryllacrididae (Raspy Crickets and Leaf-Rolling Crickets)

This large family includes nearly 800 described species placed in over 90 genera. However, it is likely that these numbers represent only a fraction of the actual number of species, as the faunas of Gryllacrididae of most tropical areas are virtually unknown. Most species of the family have been described from southeast Asia and Australia, but they are also known from Africa and the neotropics. North American fauna of Gryllacrididae is limited to only one species, *Camptonotus carolinensis*, and they are absent from Europe.

Species of Gryllacrididae are characterized by the globular head with often extremely long antennae, which in some species may exceed the body length four to five times. The wings are usually present but may be reduced or absent in some species. The ovipositor of females is long and thin, and in nymphs held curved backward over the body. This morphological modification may allow them to fit more easily into their burrows or rolled leaves. Leaf-rolling behavior is quite common in this family. All stages of some species, from the tiniest nymphs to adults, are capable of producing silk, which they use to bind shelters made of leaves, twigs, sand, and other material. Burrowing species living in hot, arid zones are known to insulate themselves from the heat by sewing shut the entrances to their burrows. Tegminal stridulation is absent in the Gryllacrididae but many species produce raspy sound (hence the common name) by rubbing the inner side of the femora against the sides of the abdomen. This behavior does not seem to play any role in courtship but is rather a defensive strategy, as all life stages of both sexes are known to display it. During courtship, some species of this group produce loud drumming noises with their legs or abdomen. All species of Gryllacrididae are nocturnal. They are probably unique in the insect world in possessing individually recognizable pheromones, which allows a cricket to return to its own burrow, distinct from one of its conspecifics, after a night of foraging. Most members of the family are predators and feed on small insects. Some are extremely agile and actively hunt for prey by rapidly running along branches, searching for insects.

Rhaphidophoroidea (Cave Crickets and Camel Crickets)

Cave and camel crickets are represented by approximately 590 described species assigned to nearly 80 genera in a single family Rhaphidophoridae (Figure 6). They are distributed worldwide and at least one species is cosmopolitan. Species of

Figure 6 Rhaphidophoroidea: Camel cricket *Ceuthophilus maculatus* from northeastern USA.

this family are rather uniform in their appearance. All are completely wingless and have smooth, dorsally convex bodies. Most have long, spidery legs and similarly long and slender antennae and palps. The ovipositor is laterally flattened and often has distinctly serrated edges.

Virtually all species are associated with dark and humid habitats, such as caves and holes in the ground. Several species sometimes invade cellars and basements of houses, and one species (*Diastrammena asynamora*) is cosmopolitan in greenhouses and other man-made environments. Most species appear to be gregarious, and many individuals of different ages are found in a single colony. Many species are associated with burrows of larger animals, mostly rodents or foxes. They feed on a great variety of organic material, and some species are associated with bat colonies, feeding on guano and the bodies of dead bats. At least one species, *Pallidotettix nullarhorensis* from Australia is known to cause death of unprotected chicks of nesting birds by swarming them and feeding on their tissues.

Eumastacoidea (Monkey Grasshoppers or Eumastacids)

Introduction

Most members of this large superfamily occur in the tropics, although a few are found in temperate regions (Figure 7). Nearly 1300 species have been described and placed in approximately 300 genera in eight families. As in all Caelifera, the antennae of eumastacids are very short, but unlike other members of the suborder, one of the last few segments of the antennae always bears a small tubercle of unknown function. The thorax can be short (Eumastacidae) to extremely long (Proscopidae); and in some groups, it can have a distinct cuticular crest. The hind femora typically are long and slender, although in some forms they may be greatly shortened and not adapted for leaping. In forms with long, leaping hind legs, they are characteristically splayed outward from the body when the insect is at rest. Wings are frequently reduced or absent, but when present they are very long and characteristically widened toward the end of the body. The tegmina are frequently transparent or semitransparent. The abdominal

Figure 7 Eumastacoidea: Monkey grasshopper *Lophothericles* sp from South Africa.

auditory organ is absent in most species of the superfamily. Little is known about the biology of members of this superfamily. None of the species appear to stridulate. Many species are arboreal, but some live on grasses in savanna-like environments and frequently have strongly elongated bodies, perfectly mimicking blades of grass (Australian Morabidae). Eggs are laid in batches in soil; but unlike those of other grasshoppers, they are never bound together by a foamy mass.

Major Lineages

Eumastacidae (Monkey Grasshoppers)

The larger of the two families in this superfamily, the Eumastacidae includes more than 230 species in nearly 50 genera, distributed in the Americas, Madagascar, and southern Asia. Body size in this family is small (10 mm) to medium (45 mm). The pronotum is always short, and the front and middle legs are relatively short. Hind legs are saltatorial and usually held widely spread, nearly horizontally. The male genitalic structures are very complex and of great value in taxonomic research. The ovipositor of females is short, with strongly serrated edges.

Proscopiidae (False Walking Sticks or Proscopids)

Proscopids are restricted in their distribution to South America, barely reaching the southernmost part of the isthmus of Panama. Approximately 215 species are known, placed in 33 genera. This family is readily distinguishable from other grasshoppers by their greatly elongate, twig-like appearance. Some species may reach a length of 165 mm, whereas the smallest are about 25 mm long. The head of these insects is unusually long and pear shaped, with large eyes situated near its narrow tip. The thorax is long and slender, and the front and middle legs are well separated. Femora of the hind legs are characteristically thickened at their bases and are not adapted for jumping. Virtually all species are completely wingless. Most species live on bushes and trees, and a few in savanna-type habitats. One species has occasionally been injurious to crops.

Figure 8 Pneumoroidea: Bladder grasshopper *Bullacris* sp from South Africa.

Pneumoroidea (Bladder grasshoppers or Pneumorids)

This small group of grasshoppers includes some of the most unusual orthopterans living today (Figure 8). The superfamily includes only 17 described species, placed in 9 genera of the single family Pneumoridae, restricted in their distribution to southern and eastern Africa. Bladder grasshoppers are large (50–100 mm) insects, with the wings either fully developed or somewhat reduced. The pronotum is greatly enlarged, forming a triangular helmet covering a large part of the body. The most unusual feature of the members of the superfamily is the shape and size of the male's abdomen, which in most species is grossly inflated, creating a balloon-like, semitransparent resonator. The stridulatory apparatus consists of a dozen or so cuticular ridges on the third abdominal segment. Thanks to the abdominal resonating chamber, the sound made by the males is among the loudest sounds produced by any insect. Females are capable of producing sound as well, but lack the abdominal stridulatory apparatus. Common among some species of this group of grasshoppers is the occurrence of sexual parasitism, where so called "satellite males" do not stridulate and develop the appearance of short-winged females. This allows them to remain close to a calling male without eliciting a territorial, aggressive response from him, and intercept females attracted to the song of the caller. Long-winged species are sometimes called "flying gooseberries" as they are frequently attracted to lights. Males who have the misfortune of being attracted to campfires explode like balloons if they fall into the fire.

Tanaoceroidea (Desert Long-horned Grasshoppers)

This small superfamily includes only three species of small grasshoppers, living on shrubby vegetation in deserts of southwestern North America. They differ from other grasshoppers in the development of their antennae, which are exceptionally long, as long as or longer than the body of the insect (other Caelifera have antennae that are shorter than half of the body length). All three known species are completely

Figure 9 Acridoidea: Lubber grasshopper *Taeniopoda reticulata* from Costa Rica.

wingless and are active during winter and early spring months, but virtually nothing is known about their biology.

Acridoidea (Grasshoppers and Locusts)

Introduction

Grasshoppers and locusts form the largest lineage of the Orthoptera, with more than 7750 species in more than 1700 genera assigned to 11 families (Figure 9). They are distributed worldwide, and although they are most diverse in tropical and subtropical regions of the world, they also occur in cold subpolar regions and high in the alpine zones of the mountains. The body size of these insects ranges from less than 10 mm to more than 120 mm, with a wingspan of 250 mm. The body form and the head shape are diverse, ranging from short and bulky to extremely elongate and slender. The antennae are always short and relatively thick, but often modified to form comb- or club-like structures. The hind legs are always distinctly thickened toward the base and always adapted for leaping. The wings vary from fully developed to completely absent. Fully winged forms have relatively narrow tegmina that are not widened toward their apices. Stridulatory organs are present only in some families and usually consist of a modified vein on the tegmen, against which the inner side of the hind femur is rubbed. The abdomen usually has lateral auditory structures, even in silent and wingless species. The female's ovipositor is always very short, with the upper and lower portions (valves) distinctly divergent at the apex. Eggs are laid primarily in the soil and are always protected with a foamy mass produced with special glands in the female's abdomen.

Most grasshoppers are diurnal, although nocturnal species are also known. They inhabit nearly all terrestrial habitats and a few species are aquatic (Pauliniinae). Open steppes and savannas of warmer regions of the world have particularly rich faunas of grasshoppers, but tropical rain forests have their share of unique forms too. Grasshoppers are also relatively

diverse in temperate zones, with some species crossing the polar circles. A number of alpine species are adapted to activity in very low temperatures. Some of these forms exhibit the interesting behavior of changing their body color depending on air temperature. In cold weather, they become much darker, and thus more likely to absorb sun rays (*Kosciuscola*).

Virtually all species of grasshoppers are exclusively phytophagous. Opportunistic cannibalism has been observed in a few rare instances, but only under crowded conditions. Most grasshoppers are polyphagous, feeding on a number of plant species, although some grasshopper species are monophagous, feeding on only one species of plant throughout their life. Such species tend to feed on plants rich in toxic secondary compounds, and in doing so, they become unpalatable to potential predators themselves. They often advertise their toxicity with bright, aposematic coloration, and there are confirmed cases of human fatalities after eating certain African species of the family Pyrgomorphidae.

A few grasshopper species, mostly of the subfamilies Cyrtacathacridinae, Oedipodinae, Calliptaminae, and Melanoplinae, are serious agricultural pests and cause enormous losses to crops every year. They form huge swarms, which on descending on fields can devour the entire annual crop within minutes. Single swarms of the African plague locust *Schistocerca gregaria* may fan out over hundreds of square miles and consist of 50 billion (50,000,000,000) individuals, weighing approximately 70,000 tons. Densities may reach 200 million locusts per square mile (500 million km⁻²). In most species of locusts, this kind of behavior is seasonal, and some have two distinct morphological forms, the so-called solitary and gregarious phases. Sometimes the differences between the solitary and gregarious phases are so dramatic that they have been described as different species. The solitary forms occur in low densities, and usually have shorter wings and cryptic coloration. Under certain conditions, especially following rains, the densities of these grasshoppers increase dramatically, prompting great physiological, morphological, and behavioral transformations. Their coloration changes, usually to black and yellow, and they exhibit a tendency to form tightly packed groups that start marching across the land. On reaching the adulthood and the ability to fly, they take off in huge swarms, usually following the prevailing winds of a cold front that could lead them to areas of fresh vegetation.

Controlling massive outbreaks of grasshoppers is difficult, and many different chemical and biological agents have been used. As one can imagine, controlling a cloud of insects stretching across hundreds of miles is a nearly impossible task. Therefore, the most effort is directed toward controlling the young, freshly emerged bands of hoppers or destroying eggs laid in areas that are likely to originate massive outbreaks. Fungal pathogens have been quite successful in combating locusts, but the survival of fungal spores in arid conditions, where many locust species live, is limited.

Major Lineages

Pamphagidae (Earth Hoppers or Pamphagids)

Members of this family are large, robust grasshoppers, seldom smaller than 30 mm and often up to 90 mm long. More than

550 species in 94 genera have been described, mostly from arid regions of Asia and Africa, with a few representatives in southern Europe. Sexual dimorphism is often marked, with males in general being significantly smaller and often fully winged, as opposed to completely wingless females. The surface of the body is frequently rough and uneven, and many species blend superbly among rocks and pebbles. Some South African species (*Trachypetrella*) have been dubbed “living rocks.”

Defensive stridulation is common in both nymphs and adults of many species, and it is achieved by various mechanisms (often more than one stridulatory mechanism is found in a single species). The typical advertisement stridulation is rare but, if present, the sound produced by males by rubbing their hind legs against the tegmina is exceptionally loud (*Lobosceliana*).

Romaleidae (Lubber Grasshoppers)

This family includes nearly 500 species in more than 100 genera, distributed mostly in warmer regions of North and South America. Romaleidae are large grasshoppers, usually strikingly colored. Species of *Tropidacris* and *Titanacris* are some of the largest orthopterans, with wingspan reaching 250 mm. The pronotum in the members of this family is often strongly keeled or crested. Wings, if present, have dense venation, and the hindwings often have a unique stridulatory mechanism formed by numerous fine teeth on one of the veins. Sound is produced by rubbing this vein against the underside of the tegmen. In addition to stridulation, some species produce a hissing sound by expelling air through their thoracic spiracles. Lubber grasshoppers have little economic significance, although a few species can defoliate trees on tropical plantations. In the USA, the best-known representative of this group is the Florida Lubber Grasshopper (*Romalea microptera*), a large and colorful grasshopper frequently used to study insect internal anatomy and external morphology.

Acrididae (True Grasshoppers and Locusts)

This is the largest family of Acridoidea, with nearly 6500 species in more than 1420 genera and 25 subfamilies. They occur in all regions of the world, and in nearly all terrestrial and semiaquatic habitats. Their body size ranges from less than 5 mm to approximately 100 mm. Body form and shape are varied, from robust and stocky to exceptionally slender and elongate. Wings can be fully developed, reduced, or entirely absent. Wing polymorphism is common in some groups (Gomphocerinae). Abdominal tympanal organs are generally present, absent only in some wingless forms. Many species stridulate by rubbing their hind femora against modified veins on the tegmina. Sometimes, an expanded area on the tegmen forms a membranous “speculum,” which acts as a resonator.

All species of locusts and most other economically important grasshoppers belong to this family. Also, most grasshoppers common in temperate zones of the world belong here, and nearly the entire grasshopper fauna of Australia is the result of a massive adaptive radiation within one of the lineages of this family (Catantopinae). Members of the small subfamily Pauliniinae are unique among other grasshoppers in

their nearly fully aquatic lifestyle. They are capable of skating on the surface of the water, diving, and swimming, and their eggs are laid on stems of submerged aquatic plants. The hind tibiae are flattened and widened at their apices, forming effective swimming paddles. Only two genera with five species belong to this family, and their original distribution was restricted to South America. Recently, one species (*Paulinia acuminata*) has been deliberately introduced to Africa in an effort to control the noxious aquatic plant *Salvinia*. This is probably the only example thus far of a truly beneficial species of grasshopper.

Pyrgomorphoidea (Gaudy Grasshoppers)

Approximately 470 species are known in this family, placed in more than 150 genera. They are distributed mostly in the tropics of the Old World, with only a few species known from Mexico and Central American countries.

The body is usually large, often reaching 90 mm. The pronotum is quite variable in form, sometimes adorned with granules or spine-like processes. Pyrgomorphae do not use sound in their courtship behavior, but some make rustling noises with their wings when alarmed. Many members of this family have warning (aposematic) coloration, a characteristic frequently associated with their toxic properties (Figure 10). Some species eject protective froth or irritating fluids as a defense mechanisms, and quite a few species are poisonous. Some species are gregarious, especially during their early nymphal stages. A few have been known to cause serious damage to crops in Africa (*Zonocerus*).

Trigonopterygoidea (Leaf Grasshoppers and Wingless Desert Grasshoppers)

This small group of grasshoppers includes only 21 species and seven genera, divided into families Trigonopterygidae (leaf grasshoppers) from southeast Asia and Australia and Xyronotidae from southwestern North America (desert wingless grasshoppers). Leaf grasshoppers are associated with humid, dense forests, and in their morphology resemble dry, brown

Figure 10 Pyrgomorphoidea: Gaudy grasshopper *Zonocerus elegans* from South Africa.

Figure 11 Tetrigoidea: Pygmy grasshopper *Afrolarcus aequalis* from Guinea.

leaves. Desert wingless grasshoppers are found in desert habitats, and they differ from other grasshoppers in the unique structure of the male copulatory organs (cerci), which resemble enlarged, multibranched antlers.

Tetrigoidea (Pygmy Grasshoppers or Grouse Locusts)

This interesting lineage of the Orthoptera includes approximately 1660 species in nearly 260 genera, placed in one family, Tetrigidae (some authors divide this superorder into two families: Tetrigidae and Batrachideidae) (Figure 11). Most species of pygmy grasshoppers are tropical but a few occur in temperate zones, often at very high elevations. Their body size is generally small, seldom exceeding 20 mm. The pronotum is always greatly enlarged, covering the entire body and often extending far beyond the end of the abdomen. Sometimes the pronotum is vertically expanded, forming a large crest or a leaf-like lobe. A few species display a pronounced polymorphism in the development of the pronotum and wings. Wings are usually present but may be reduced or absent in some forms. The tegmina are always reduced to small, oval lobes, with greatly reduced venation. The hindwings are well developed, fanlike, and usually completely concealed under the pronotum. The hind femora are very stout and all tarsi lack the arolium between claws. Members of Tetrigoidea have neither stridulatory organs nor the abdominal auditory tympana. Most species are associated with moist or semiaquatic habitats. Many can swim very well and dive when threatened. Some species are arboreal and many live on bark of trees in tropical forests. Pygmy grasshoppers feed on a variety of small plants, such as mosses, as well as on lichens and algae. They have little economic importance, although some may cause some damage in rice plantations.

Figure 12 Tridactyloidea: False mole cricket *Ripipteryx* sp from Guyana.

Tridactyloidea (False Mole Crickets and Sandgropers)

This superfamily includes approximately 230 species in 17 genera divided among three families (Figure 12). Most species are small, 4–15 mm in length, although some sandgropers (Cylindrachetidae) can reach the length of approximately 40 mm. Families Tridactylidae and Ripipterigidae have characteristically modified hind tibiae, which bear a pair of long, apical flaps, whereas the tarsi are strongly reduced. Their tegmina, if present, are short and leathery and sometimes have a row of stridulatory pegs. The Tridactylidae are distributed worldwide, whereas the Ripipterigidae are restricted to Central and South America. They inhabit wet and semiaquatic habitats and some of them make dense networks of shallow burrows in the mud. The Cylindrachetidae are restricted to Australia and New Guinea, and one species is known from Patagonia. The body is strongly elongated and completely wingless. The pronotum is greatly elongated and cylindrical, with its lateral edges strongly curved downward, nearly meeting on the underside of the thorax. The front legs are modified for digging, and the second and third pairs are shortened. Sandgropers spend their entire lives underground in sandy soils. They are omnivorous, feeding on plants as well as insects and their larvae. Sandgropers produce odorous defensive secretion from a pair of abdominal glands.

Glossary

Arrhenotoky Reproductive mode in which unfertilized eggs develop into haploid males and fertilized eggs develop into diploid females.

Eusociality Cooperative behavior among individuals of the same species characterized by reproductive division of labor, overlap of generations, and cooperative nesting.

Holometabola Insects characterized by complete metamorphosis, a wingless larval stage, and an intermediate pupal stage.

Idiobiont A parasitoid that develops on a paralyzed, incapacitated host.

Koinobiont A parasitoid that develops on a mobile, active host.

Monophyletic A group in which all species are descended from a single common ancestor and all descendants of the ancestor are classified in the group; characterized by shared derived characters.

Ovipositor Modified appendages of the seventh and eighth abdominal segments used for egg laying.

Paraphyletic A group in which only some of the species descended from an ancestor are classified together; characterized by shared ancestral characters.

Parasitoid An organism in which the immature stage feeds and develops on a single host arthropod, resulting in the death of the host.

Parthenogenesis Reproduction in which eggs are not fertilized by males.

Phylogeny Branching pattern of evolutionary relationships among organisms.

Phytophagy Plant feeding, herbivory.

Thelytoky Reproductive mode in which unfertilized eggs develop into diploid females.

The insect order Hymenoptera comprises a vast array of species that are familiar to even the most casual observer. The group includes the ants, bees, and wasps as well as less well-known groups such as the chalcids, ichneumons, sawflies, and the wood wasps. Hymenoptera are extremely common on all the continents of the world, except Antarctica. Hymenoptera range in size from microscopic species less than 1 mm in length as full-grown adults to species in which the females are 10 cm or more in total body size. Hymenoptera are holometabolous insects, generally characterized by mandibulate mouthparts, complete metamorphosis, and two pairs of membranous wings. One striking feature is that the vast majority of species are characterized by arrhenotokous parthenogenesis: Fertilized eggs develop into diploid females and unfertilized eggs ultimately develop into haploid males. Adult Hymenoptera generally feed on nectar, honeydew, or other sugar sources, but some are actively predaceous. The larvae have a wider variety of feeding habits: Some feed on plants or fungi, whereas others feed on animals, as predators or parasitoids. The larvae of bees and a few other groups feed on provisions of pollen collected and stored by the parent female. The egg-laying appendages, the ovipositor, are often specialized to place the eggs on or into the plants or arthropods that will serve as the food source for the developing larvae. In one large group, the Aculeata, the ovipositor is modified into the sting, a structure that primarily serves to deliver toxic venoms to paralyze the prey or is used in defense. The Hymenoptera are also noteworthy for the evolution of social behavior in several groups. The most highly developed form, eusociality, has arisen many times within the order among the bees, wasps, and ants.

Classification

Hymenoptera has been traditionally divided into two suborders, the Symphyta and the Apocrita. The Symphyta comprise the sawflies and wood wasps (Gauld and Bolton, 1988; Goulet and Huber, 1993; Hanson and Gauld, 1995; Naumann, 1991). The larvae of the vast majority of species in this suborder consume plant or fungal material, feeding on leaves or stems, feeding within galls produced in the host plant, or boring within stems or trunks of woody plants. Symbiotic fungi comprise a significant part of the diet of many of the wood-boring species. Sawfly larvae that feed externally on leaves are generally eruciform, i.e., caterpillar-like in form, with well-developed thoracic legs, abdominal prolegs, and sclerotized heads.

The suborder Apocrita descends from a symphytan ancestral species. As adults, the first abdominal segment of the Apocrita is intimately associated with the thorax and separated from the following segments by a mobile constriction. This segment is called the propodeum. Thus, the locomotory tagma of the body, bearing the legs and wings, is four segmented. The larvae are generally immobile and highly simplified in structure. Apocrita are generally characterized by larvae that feed on other arthropods, including predatory species in which one larva feeds on several prey items and parasitoids in which the larva feeds on a single host individual. Parasitoids are distinguished from parasites in that the host of the former is usually killed as a result of feeding. Thus, ecologically, parasitoids function as predators, feeding on and ultimately killing their host. The parasitoid life history is also found in the closest living relative of Apocrita within the Symphyta – the

family Orussidae. However, numerous apocritan groups are secondarily phytophagous, consuming seeds or pollen or forming galls in plant tissue within which the larvae feed and develop.

The division of Hymenoptera into two suborders is still generally used, even though recent evidence indicates that the Symphyta are paraphyletic. In the formal taxonomic classification, approximately 22 superfamilies and 89 families are recognized in the extant fauna (Sharkey, 2007). The Tenthredinoidea, Pamphilioidea, Cephioidea, and Xyeloidea comprise the phytophagous sawflies. Wood wasps comprise families within the Siricoidea and Xiphydrioidae. In the Apocrita there are many small, relatively primitive superfamilies of parasitoids: Trigonalyoidea, Ceraphronoidea, Evanioidea, Megalyroidea, and Stephanioidea. The superfamilies Chalcidoidea, Cynipoidea, Ichneumonoidea, Proctotrupoidea, Diaprioidea, and Platygastroidea encompass the vast majority of parasitoid species. Many of these are common and extremely abundant. The family Ichneumonidae is estimated to contain more than 22,000 known species, with many others yet to be recognized. The remaining three superfamilies – the Chrysidoidea, Vespoidea, and Apoidea – make up the aculeate, or stinging Hymenoptera. The Chrysidoidea include many relatively small families of parasitoids. The Vespoidea contains the ants, velvet ants, hornets, spider wasps, paper wasps, and potter wasps (Hölldobler and Wilson, 1990). The Apoidea are the bees and predatory wasps (Michener, 2007).

The order Hymenoptera is estimated to contain approximately 115,000 described species (Gauld and Bolton, 1988). This is only a rough indicator of the actual total because hundreds of new species are described each year in the taxonomic literature. The largest families are the Ichneumonidae (more than 20,000 species), Braconidae (approximately 12,000 species), Formicidae (the ants, with more than 12,000 species). Austral disjunct distributions are characteristic of a relatively few families of Hymenoptera, such as Megalyridae and Plumariidae. The major groups are found in all biogeographic realms or perhaps limited to the tropics, such as the fig wasps or Agaonidae. Ichneumonids and sawflies appear to be the most diverse in the temperate realms.

Phylogeny and Fossil Record

The oldest fossil Hymenoptera are found in deposits from the Triassic period of the Mesozoic. These include some species that are closely related to living sawflies. Parasitoid wasps, as inferred from their structure (especially the elongate ovipositor in some species) and their relationships to living species, first appear in the Jurassic. The oldest fossils of social insects, ants and bees, have been found in Cretaceous impressions and amber nodules. Minute parasitic Hymenoptera and ants and bees are commonly found in Cenozoic amber from the Baltic, the Dominican Republic, and Mexico.

Although Hymenoptera are clearly members of the monophyletic group Holometabola, comprising insects with complete metamorphosis, their position within that huge complex is unclear. Most workers place them as a basal group, sometimes as the sister group to all other holometabolous orders. Within the Hymenoptera, the basal position of

Symphyta is supported by evidence from morphology, behavior, molecular sequences, and the fossil record. The historical grouping of parasitoid species into a taxon variously called Parasitica or Terebrantes, although of some practical use, does not reflect the pattern of phylogenetic relationships among them. The relationships among the basal Apocrita are still unclear. Many of these species are parasitoids of wood-boring Coleoptera, a life history shared with their closest living relatives in the Orussidae. Numerous hypotheses of relationships and classifications have been offered through the years that have been based on varying amounts of evidence from several sources and analyzed more or less rigorously, but none has yet achieved anything approaching general acceptance. The Aculeata are a well-supported monophyletic group, and a fair amount of progress has been made in elucidating the relationships among its constituents.

Biology

General

Reproduction

Arrhenotokous parthenogenesis, or haplodiploid reproduction, is characteristic of the vast majority of species of Hymenoptera and is generally thought to have been very important in its evolution. In this mode of reproduction, the offsprings are produced from both the fertilized and unfertilized eggs. The eggs that are not fertilized develop into haploid males. The fertilized eggs develop into diploid embryos, and these are usually females. Because of the mechanism of sex determination in Hymenoptera, which is not completely understood, diploid males are rarely produced. Mated adult females store spermatozoa received from the males during mating in a diverticulum off of the reproductive tract, the spermatheca. The female is capable of controlling the release of spermatozoa to fertilize eggs passing through the oviduct, thus controlling the sex of her offspring. The control of the sex ratio of offspring may be advantageously applied, in theory, to maximize the reproductive success of the female. In some parasitoid species, the size of the host can influence the female to lay a male or female egg. In other circumstances, the presence or past presence of other ovipositing females on a host has been shown to influence the relative proportions of male and female eggs laid. Haplodiploidy also affects the proportions of alleles that are shared among the relatives in comparison to the expectations of relatedness that are commonly found among strictly diploid species. In the simplest case of a female mating with one male, a daughter may be generally expected to share a greater proportion of its alleles with her sister (75%) than with her brother (25%). The two female offsprings share one set of chromosomes contributed by the haploid male spermatozoa and, on average, would expect to share 50% of the alleles inherited from the mother. In contrast, the male offspring has only a single set of chromosomes derived from his mother. This asymmetry in relatedness has been thought to be a contributing factor to the multiple evolution of eusociality in the Hymenoptera, but its importance is strongly questioned. Although single matings may be the rule for many species under normal conditions,

one female mating with many males is not uncommon. The mating flight of the honeybee, *Apis mellifera*, is an extreme example. Also, many species of social insects, especially among the ants, have numerous unrelated egg-laying queens within a colony.

Another form of parthenogenesis is relatively common within Hymenoptera: thelytoky. In this case, the female does not mate with a male, and her unfertilized eggs are capable of embryonic development and produce only female offspring. Thelytoky is not uncommon among parasitoid groups, and the funneling of all reproductive output into the production of new egg-laying daughters maximizes short-term reproductive success. It has recently been discovered that in several cases thelytokous parthenogenesis is caused by bacterial infections, principally by the genus *Wolbachia*. Treatment of the wasps with heat or antibiotics can cause the individuals to revert to normal arrhenotokous modes of reproduction. Many strains of *Wolbachia* do not result in thelytokous reproduction but rather in cytoplasmic incompatibility between eggs and spermatozoa. Infections by these bacteria have been discovered in a wide range of insects and evolutionary and ecological significance of the phenomenon is not well understood.

Oviposition Behavior

Hymenoptera are probably most familiar as stinging insects. The sting apparatus is a modification of the egg-laying appendages fundamental to all Hymenoptera. Because egg-laying structures are naturally associated with females, only female wasps can sting. However, the males of some species are extraordinarily adept at mimicking both the structure and behavior of females and can sometimes fool even experienced workers.

In its ancestral condition, the ovipositor is composed of two pairs of elongated appendages, the gonapophyses or ovipositor valves, associated with the seventh and eighth abdominal segments. The gonapophyses are physically linked together and function as a single articulating unit. When not in use, the ovipositor is usually enclosed within a protective pair of sheaths, the gonopods. In sawflies, the gonapophyses are laterally flattened, serrate, and used to cut an incision into plant material into which one or more eggs are laid. The similarity in structure and function to a saw gives rise to the common name for most of the Symphyta.

Within the Hymenoptera, the ovipositor and its function have been extended beyond its basic function in egg laying. Among parasitoids, it is used to paralyze hosts; in the Aculeata or stinging Hymenoptera, the ovipositor and venom are often used as a defensive weapon.

Parasitoids

A parasitoid is defined as an animal in which the immature stage feeds on a single host individual, and this feeding activity normally results in the death of the host (Quicke, 1997). Historically, such insects have been called parasites, but this was misleading. True parasites, such as lice, feed on a large host but the feeding activity has only a minor deleterious effect. Despite this distinction in names for the two types of life

history, the verb parasitize is still normally used to describe the action of both groups. A parasitoid is essentially a predator, but one that feeds on and kills only a single prey item. They also differ from predators in that it is the parent that finds the prey and the offspring that feed on it. The Hymenoptera are the primary group of insect parasitoids, but other orders, particularly the Diptera and Coleoptera, have species that follow this same pattern.

Parasitoid Hymenoptera attack a very broad range of arthropods. Practically all other insect groups, as well as many arachnids and myriapods, have their suite of parasitoids. Most parasitoids attack the immature stages of their host: the egg, nymph, larva, or pupa. A few groups parasitize adult insects. In some cases, the female parasitoid oviposits on one stage and her adult offspring emerge from another. For example, some species of Braconidae oviposit within the egg of their host, but the wasp larva actually feeds on and emerges from the host larva. After the completion of feeding, the parasitoid pupates on, within, or sometimes near the spent carcass of its host.

The ovipositor is used to first sting the host arthropod, and venom is then injected. The venom may incapacitate the host for only a short period of time or, in more extreme cases, may result in the complete suspension of most normal activities, putting the host in a state of suspended animation. The female wasp then lays one or more eggs on or often within the body of the host. In some species, the female parasitoid attacks exposed hosts – for example, a caterpillar feeding on a leaf. In other cases, though, the hosts are hidden in the soil, enclosed within shelters made of leaves, twigs, debris, or silk, or even bore deep within the trunks of trees. The structural characteristics, sensory capabilities, and behavioral repertoire of the female wasp combine to enable her to locate and successfully oviposit on such protected, cryptic hosts. For example, many species of parasitoid Hymenoptera that attack wood-boring beetles are equipped with elongate ovipositors that may be two or more times the length of the rest of the body. The females are capable of drilling through tens of centimeters of wood with their ovipositor in order to find and parasitize the hidden beetle larva.

The proximate mechanisms by which a female parasitoid locates, identifies, and determines the suitability of hosts within a complex environment are only beginning to be understood. Chemical cues are certainly important in all of these stages of host finding. These chemicals may be produced by the hosts as a by-product of normal activity such as feeding. Often, parasitoid females are attracted to volatile chemicals produced by the plant on which a host is feeding. Other sensory modalities used in finding hosts and assessing their quality include vision, tactile examination, detection of substrate vibrations, and possibly heat detection. The external surface of the body of an adult wasp is studded with an array of sensory structures. For host location and acceptance, the most important of these are found on the antennae, tarsi, mouthparts, and ovipositor.

Among the array of details of life-history strategies, two general patterns are often distinguished, and parasitoids may be classified as idiobionts or koinobionts. Idiobionts are generally characterized by the fact that the development of the host arthropod is arrested through the action of the venom

injected by the parent. The larval parasitoid thus develops on an incapacitated host. In koinobionts, the host resumes feeding and development after the parasitoid female has oviposited. The larval koinobiont parasitoids typically develop within the body of the host, but this may be delayed for some time as the host grows and even pupates. Thus, the parasitoid must have the physiological mechanisms to evade the immune system of its host. Idiobionts typically attack hosts that are found in concealed situations and a broad taxonomic range of hosts may be attacked. Koinobionts, in contrast, may parasitize only exposed hosts and, because they must be attuned much more closely to the host immune and endocrine systems, their host range is typically much narrower.

There is a tremendous range of variation found within the general life-history patterns described. Parasitoid larvae may feed on the host from outside the host's body as ectoparasitoids, or they may live and feed within the body of the host as endoparasitoids. Among solitary parasitoids, a single individual wasp develops from each host individual. The adult that emerges from the pupa then must locate mates, food, water, and new hosts on which to oviposit. Many individual parasitoids develop on a single host in gregarious parasitism; the number of wasps may range from two to thousands. In these cases, males generally emerge first and mate with the later-emerging females on or near their pupation site. In some cases, this leads to a high level of sib-mating (i.e., brothers mating sisters), and in such situations it is not uncommon for the sex ratio to be significantly skewed toward the production of females. In other words, the parent female seems to lay just enough male eggs, sometimes only one, to ensure the insemination of all her daughters. In this manner, she is thought to be able to increase her overall reproductive output. Gregarious parasitism may be effected by numerous wasps attacking a single host, by a single wasp placing more than one egg on or in the host, or by a peculiar phenomenon called polyembryony. In this case, the female parent places one egg within the body of the host, but this single egg produces from two to thousands of identical embryos, each of which eventually develops into a new adult parasitoid. Polyembryony has apparently evolved at least four times within the Hymenoptera because it is found in the families Braconidae, Platygasteridae, Dryinidae, and Encyrtidae.

Hyperparasitoids, or secondary parasitoids, are species that are actually parasitoids of other parasitoids. For example, in some species of the family Trigonidae, the adult female lays large numbers of eggs of foliage near feeding caterpillars. The tiny eggs are ingested by the caterpillar, the thick shell of the egg is disrupted by the caterpillar's mandibles, and the trigonalid larva quickly hatches and bores through the gut of the host to enter the hemocoel. It then lies dormant until the caterpillar is subsequently parasitized by another parasitoid species, typically an ichneumonoid or a tachinid (Diptera). The new parasitoid develops on the caterpillar host but is then attacked and ultimately killed by the trigonalid. Success in such a complicated life history requires a sequence of individually unlikely events: ingestion of the egg; survival of the host caterpillar from disease, predation, starvation, etc.; and subsequent parasitization of the caterpillar by a suitable species. The low probability of such a sequence is compensated by the fact that the female trigonalid lays huge numbers of eggs.

One of the most bizarre types of life history is the heteronomous parasitism found among some species of the chalcidoid family Aphelinidae. Female offspring develop as primary endoparasitoids of sternorrhynchous Hemiptera (e.g., scale insects). The males, in contrast, may develop as ectoparasitoids of the same species of host or as secondary parasitoids, sometimes attacking females of their own species.

Although the parent female of most parasitic Hymenoptera finds and oviposits on the host for her offspring, in a few cases it is the larvae that locate the hosts. In the Perilampidae and Eucharitidae, the adult female wasp lays her eggs on or in plant material, often in large numbers. The first instar larvae that hatch from these eggs are strongly sclerotized and mobile, in contrast to the typical larva of Apocrita. These mobile first instars, called planidia, somehow find their way to their host, attach, and feed. In the eucharitids, it appears in some species that the planidia may attach to thrips, which are then picked up and carried by ants into their nest. Once there, the planidia disengage from their temporary transport and attach to and feed on ant larvae.

Predators

The distinction between hymenopteran larvae that act as parasitoids and those that act as predators is fairly arbitrary, being dependent only on the number of host individuals killed and eaten in the process of larval development. The typical predatory life history is extremely similar to the idiobiont strategy. The parent female wasp finds, stings, and immobilizes the prey item. The prey may already be in a place of concealment, such as beneath a rock or within a burrow, or the female wasp may actually construct a hiding place, often a burrow in the soil or tunnels in wood. More than one prey item may be cached in a chamber in this burrow, and then the female wasp lays an egg on the prey. The larva that hatches feeds on and develops on this store of food that has been provided by its mother. In the case in which only one prey item is available, this is essentially identical to the life history of an external parasitoid. In many species, the female parent may use the same burrow within which to store the prey for several of her larvae, constructing side chambers for each of the offspring or building chambers in a linear series. Thus, from the starting point of ovipositing on a paralyzed prey item within its own hiding place, there is the development of a nest – that is, a structure built by the female parent within which her young are fed and develop. Some wasps gather together all of the prey that an offspring will need for development before ovipositing. Others progressively provision their nests, providing new prey items to the developing larva as it consumes the food available.

Phytophagy

It is generally accepted that the Hymenoptera evolved from a phytophagous ancestor similar in many respects to the extant sawflies. The Apocrita, in turn, are derived from a parasitoid ancestor. However, within the Apocrita, there are numerous cases in which phytophagy, in its broadest sense, has re-occurred. In some cases, such as the seed chalcids of the family

Eurytomidae, the host relationship is fairly straightforward: The female wasp oviposits into the developing seed and the larva feeds on the endosperm. In other cases, their phytophagy is more elaborate or even bizarre.

Gall Makers

Galls are abnormal growths of plant tissue caused by some sort of stimulus from another plant or animal. A wide range of insects are known to cause gall development; within the Hymenoptera it is found among sawflies, the primarily parasitic Braconidae (Ichneumonoidea) and Chalcidoidea, and especially in the gall wasps, the family Cynipidae (Cynipoidea). Gall development is induced either by chemicals injected into the plant by the ovipositing female or by secretions produced by the newly hatched larvae. The plant tissue that is elaborated into the gall may take a variety of shapes and sizes, from mere swellings of the stem to large, ornate structures on the leaves or roots. The gall maker feeds on the plant tissue within the gall, pupates there, and eventually chews an emergence hole through which it escapes. The nutritive tissue, both that of the gall and sometimes that of the developing gall maker, is also made use of by a wide variety of inquiline species which oviposit into the gall and kill the original gall maker.

The life histories of cynipid species may vary greatly. Some are fairly typical of other Hymenoptera, that is, males and females emerge from their respective galls and then mate, and the females then seek out new host plants in which to oviposit. Their eggs develop into either females or males, depending on whether the eggs are fertilized or not. Such species are typically univoltine and attack a wide variety of host plants. Other life histories may be significantly more complicated. Some species have simply abandoned the production of males and are strictly thelytokous. Others alternate between sexual and asexual generations, reproducing via arrhenotokous and thelytokous parthenogenesis, respectively. The sexual generation consists of both males and females. These mate and the inseminated females seek hosts in which to oviposit. All of the offspring of these wasps develop into females. The adults of this new generation in turn oviposit, and some of the eggs develop into males and some into females, thus returning to the sexual generation. The adults of the sexual and asexual generation of gall wasps often strikingly differ in their structure and produce very different types of galls in different positions on the host plant. In some cases, they even attack different species of plants.

Fig Wasps

The fig wasps, of the chalcidoid subfamily Agaoninae, are very specialized forms of gall makers. Female fig wasps burrow their way into the syconium, the inflorescence of the fig plant. Pollen from the body of the female is transferred to the flowers concealed within the syconium and then the female oviposits within some of the flowers. These flowers subsequently swell, and the emerging larva feeds within the tissues, consuming both the embryo and endosperm. The male wasps then emerge first and mate with the females while they are still within the galled flowers of the fig. The females later emerge from the flowers, pick up pollen, sometimes actively storing it in special cavities on the body, and escape through holes chewed by the males. Male fig wasps are extraordinarily

aberrant creatures: They lack wings, their eyes and antennae are underdeveloped, but in contrast the legs and mandibles are sometimes enormous. A rich complement of other parasitic Hymenoptera are associated with figs, some developing on fig tissues and others acting as parasitoids of the fig wasps.

Leaf-Cutting Ants

The leaf-cutters belong to the tribe Attini (Formicidae). These ants are found nearly throughout tropical America, north into the southern portions of the US. The long lines of thousands of ants, pruning pieces of vegetation and carrying them back to the nest are a familiar sight throughout the New World. Strictly speaking, the leaf-cutters are not phytophagous because they do not feed directly on the vegetation that they collect. Rather, they use the leaves and stems as the substrate on which they maintain a fungal colony. The ants feed on specialized structures produced by their fungus; the fungal organism, in return, is nurtured and maintained in an environment favorable for growth. When leaving the nest on her mating flight, the new virgin queen takes a bit of the fungal mass to use as an inoculant when she begins her new colony. Colonies of leaf-cutters can be extremely large, numbering in the millions. As a result, they can be extremely destructive to agriculture, forestry, and horticulture.

Pollen Feeders

The life history previously described for predatory stinging Hymenoptera has been modified in at least two cases in which the parent female provisions her nest with pollen rather than arthropod prey. The largest group in which this has occurred, and one of the groups most familiar to the casual observer, comprises the bees. Female bees visit flowers both to gather nectar for their own energetic needs and to gather the pollen on which their offspring will feed. Some bees are oligolectic, i.e., they are fairly restricted in the range of plant species from which they gather pollen. Others, such as the ubiquitous honeybee, are polylectic and gather pollen from a broad range of species. There are many specializations on the bodies of bees that facilitate the transport of pollen. Some bees will ingest the pollen grains and transport them within their crop; others have dense beds of hairs particularly on the legs or on the underside of the abdomen where pollen is packed for transport. Pollination of flowers by bees – that is, the transport of pollen from one flower to another – is often accidental and is irrelevant to the insect but of critical reproductive importance to the plant. Many anatomical features of plants are believed to be specializations for attracting bees or other insects to the nectar and ensuring that pollen grains adhere to their body.

Social Behavior

Social behavior is most simply defined as that of groups of individuals of the same species that cooperate with one another. Simple aggregations of individuals may occur, for example, where some limiting resource is found, such as water or nesting sites. Evolutionarily important social behavior, however, involves some sort of cooperation among individuals leading to reproductive success of some or all of the

participants. Among the insects, the extremes in development of social behavior primarily are found in the termites (order Isoptera) and within the Hymenoptera. Its most highly developed level, called eusociality, is characterized by cooperation among females in nesting, overlap in generations, and reproductive division of labor. This means that some individuals sacrifice production of their own offspring in order to facilitate reproduction by other individuals of the same colony. Eusociality has clearly evolved several times within the order Hymenoptera: once in the ants (Hölldobler and Wilson, 1990), which are primitively eusocial; once in the family Crabronidae; and several times among the bees and the social wasps (i.e., the paper wasps, yellowjackets, hornets, etc.).

Colonies of social insects can be extremely large, both physically and in terms of total numbers of individuals. The life cycle of a colony typically begins with the mating flight of a virgin queen. After mating with one to several males, the queen begins construction of a nest in the soil, a natural cavity, or in some cases in the open. Colony founding is sometimes cooperative (e.g., in some paper wasps), and the determination of which individual will become the primary reproductive one is established through behavioral interactions among the foundresses. Males do not participate in colony founding and only serve to inseminate the new queens, after which they soon perish. The eggs produced by the queen develop into the first worker generation: These are all daughters of the queen and typically do not reproduce. Workers forage for food and nest materials, care for the developing brood, defend and care for the nest, and care for the queen. This range of behaviors is sometimes divided among the workers. In some species, individuals are morphologically specialized into recognizable castes for certain functions such as defense in the case of soldiers. Morphological differentiation into castes results from allometric growth of the individual workers. Individuals of overall larger body size have disproportionately large mandibles, spines, and head capsules. In other cases, individuals may not be morphologically distinguishable but specialize in particular sets of behaviors at different periods of their adult life, usually ending as foragers outside the nest. Once well established, the collective efforts of the individuals of the colony result in the production of a new generation of males and reproductive females. Some social species reproduce by swarming: In the case of the honeybee, the old queen leaves the existing nest, taking with her a portion of the worker force, and reestablishes in a new site. Then one of the newly emerging queens takes over the remainder of the colony.

Communication among individuals is critical to social behavior. Chemical communication is probably of primary importance. Many exocrine glands have been identified on social Hymenoptera from all major parts of the body. These chemicals include alarm and defense pheromones, mating pheromones, trail pheromones, and signals from the queen that suppress the reproduction of workers. Trophallaxis, the exchange of food between individuals, may serve as the medium of exchange of some chemical signals. Tactile behavior is also important, principally involving antennal contact between individuals. The classic example of tactile communication is the waggle dance of honeybees. The location of food sources, including direction and to some extent distance, is

transmitted to nestmates by a stylized reenactment within the darkness of the hive of the foraging flight. The direction of the resource in relation to the sun is indicated by the angle formed by the waggle portion of the dance in relation to the vertical axis within the hive.

Eusocial behavior is a fairly rare phenomenon in the animal world. The repeated evolution of such complex behavior within the single order Hymenoptera has led to a great deal of work in search of an explanation. One suggestion is that the asymmetric relationship among siblings and parents may be an important underlying feature that predisposes this group to the evolution of the characteristics of sociality. However, within the group at least two separate paths leading to eusociality have been identified. The parasocial route first envisions communal nesting among related females, followed by cooperative brood care and eventually reproductive division of labor. The subsocial route to eusociality posits first the development of overlap of generations followed by continued reproduction of the parent female in the company of her own daughters.

These characterizations of social behavior are often more simplified than the real situation found in nature. Colonies may be founded by more than one queen; sometimes these are closely related. Queens are probably usually inseminated by several or even many males, thus reducing the relevance of the asymmetry of relationships associated with arrhenotokous parthenogenesis. It is also clear that eusociality, although a highly evolved trait, is not the end point of evolution in Hymenoptera. Local environmental factors are undoubtedly important in the development of eusocial traits and in their subsequent loss. Several cases have been identified in which these behavioral repertoires and both the morphological and physiological features associated with them have been lost. Some of the most extreme cases are social parasitism in which reproductive females of one species live within the nest of another social species. The workers of the host species feed and care for the parasite, and the latter contributes nothing to the welfare of the colony. Social parasites are widely found among the ants, bees, and wasps.

Practical Import

Pests

In comparison to other large orders of insects, the Hymenoptera have relatively few species that qualify as pest species. A few of the phytophagous forms do cause some damage to agricultural crops or to trees. Leaf-cutting ants and leaf-cutter bees can cause damage by removing significant amounts of foliage from plants. In contrast to the ants, leaf-cutter bees do not feed on the leaves, either directly or indirectly, but use the pieces in order to line the brood chambers in their nests. Seed chalcids may destroy seeds of crops such as clover. Many of the phytophagous sawflies are important pests, particularly to forest trees. The family Diprionidae, which includes species such as the red-headed pine sawfly (*Neodiprion lecontei*), are often important pests of conifers. Other families such as the Tenthredinidae (e.g., the larch sawfly, *Pristiphora erichsonii*, and the birch leaf miner, *Fenusa pusilla*) and Cephidae

(e.g., the wheat stem sawfly, *Cephus cinctus*) are occasionally important.

The most significant deleterious role played by Hymenoptera is derived from reaction that humans have to being stung. Although a few species of parasitic Hymenoptera are capable of jabbing their ovipositor through the skin of a person, this usually requires that the person actually hold the wasp in his or her hand. This is not a health concern. Aculeate Hymenoptera, however, inject venom through the sting apparatus into the subject of their attention. In some cases, the venom can cause severe pain by virtue of the properties of the chemicals. The most significant hazard, though, lies with the reaction of the human immune system to the components of the injected venom. The typical response of swelling, pain, and itching may become life threatening for individuals that become hypersensitive to the components of the venom. In extreme cases, the resulting loss in blood pressure and shock can cause death, even from the sting of a single bee.

The so-called killer bees or Africanized honeybees are perceived as a serious health risk in the New World. These bees are not an aggressive exotic species that has invaded the Western Hemisphere, but rather are the same species as the honeybee that is used in apiculture throughout the world (*A. mellifera*). Colonies of the honeybee from Africa were brought to Brazil in order to try to breed some of their useful traits into the colonies of European honeybees being maintained in the tropics. Unfortunately, African bees escaped from confinement and became established as feral colonies. This strain of bees has spread and interbred with both feral and domesticated colonies of honeybees throughout South and Central America and into the southern US. The African subspecies of the honeybee is notorious because the colony more vigorously defends its nest against marauders than the European bees and is generally more sensitive to disturbance. In defense, the bees attack the animal or person disturbing the colony by stinging, just as do European bees. The difference between the two types of bees lies not in a more toxic venom but in the fact that the African forms are quicker to attack and are more persistent in pursuit and stinging. Numerous deaths of humans and livestock have been recorded that result from the high number of stings inflicted and not from hypersensitivity of the person or animal being attacked. In areas in which the honeybees have become more aggressive, greater care is needed by persons approaching the hives.

Biological Control Agents

Although some species of Hymenoptera have negative impacts on humans and their commerce, by and large the order is considered to be very beneficial. One of the most important categories of such beneficial species consists of those that either parasitize or prey on pest arthropods. These species, by eventually killing the other insects, act as biological control agents that reduce the population levels of their hosts. Such control agents have many advantages: Parasitoids are often fairly host specific, and thus their effects are focused on the pest problem; a population of biological control agents is capable of maintaining itself through time, thus providing continuous control; parasitoids are often extremely effective at

locating their hosts in a complexly structured environment; and parasitoid populations respond to those of their hosts, increasing when host populations increase and decreasing when the availability decreases. The importance of parasitoids as regulators of the populations of their hosts is most clearly seen when, for example, a phytophagous species is accidentally introduced into a new region without its normal complement of natural enemies. Populations of such species are capable of explosive growth in the new environment, rapidly becoming important pests, for example, gypsy moths (*Lymantria dispar*) in North America and the cassava mealybug (*Phenacoccus manihoti*) in tropical America. Biological control programs involve the discovery of the natural environment and enemies of such pests and the importation of these natural enemies for control. Some examples of biological control have been spectacularly successful, with effective long-term control of pests. The parasitoid families Encyrtidae and Aphelinidae have been particularly effective in biological control programs of many species of sternorrhynchous Hemiptera.

Pollination

The successful development of seeds and fruit of many species of flowering plants depends on pollination – the movement of pollen from one flower to another. Although some species of commercially important plants, particularly grasses, are wind pollinated, a great many others rely on animal agents for the transfer of pollen. Under natural conditions pollinators can include vertebrates, such as bats and hummingbirds, and a wide variety of insects, including flies and beetles. Hymenoptera, however, and in particular the bees, are extremely important as pollinators. Recall that bees provision their nests with plant pollen on which their developing larvae feed. In the process of collecting pollen for their nests and also in collecting nectar from within the flowers, pollen grains that adhere to the hairy body of a bee can be transferred to the style of the flower. Natural pollinators include a vast array of native bees, but for many commercial crops colonies of honeybees are used to effect pollination. The honeybee is a polylectic species, that is, it gathers and its larvae feed on pollen from a wide variety of plant species. Colonies are regularly transported to fields in order to temporarily increase population levels to maximize fruit and seed production.

Honey and Other Bee Products

The large colonies of social bees also store honey within the nests that they construct. Honey is the modified and concentrated product of the nectar gathered principally at flowers and is used as an energy source for the adult bees. The most familiar species that serve as sources of honey for human consumption belong to the genus *Apis*, including the domesticated honeybee, but both bumblebees and stingless bees also produce and store honey. Honey production and the sale of it often provide a significant income supplement for small farmers. Another product from honeybee colonies that is of some value is beeswax, used variously in cosmetics, pharmaceuticals, and candles.

Glossary

Hexapod Group including insects and their primitive relatives.

Instar Stage between molts of immature insects.

Pro-, meso-, and metathorax First, second, and third segments of the thorax.

Introduction

The Class Insecta, or the slightly larger Superclass Hexapoda (which additionally includes the orders Collembola, Protura and Diplura), is the world's most species-rich group of organisms, with about 1 million described species. They are found nearly everywhere on earth, including the terrestrial, aquatic, and, to a much lesser extent, marine ecosystems. They are most diverse in tropical forests, where the undescribed fauna has been estimated to comprise 5, 10, 30, or even 50 million species. Hexapods are a well-established monophyletic group, based on the presence of three major body divisions—head, thorax, abdomen—and a single pair of locomotory appendages on each thoracic segment. Some primitive insects have retained appendages on the abdominal segments, but these are much smaller and less functional than those on the thorax. Most of the more derived groups of insects also have wings, usually one pair on each of the mesothoracic and metathoracic segments, but these have been variously lost or modified in some groups, especially the Diptera (flies).

The fossil record of hexapods extends back to the earliest record of terrestrial life, with Collembola and lower insects recorded from the lower Devonian, almost 400 million years ago, and possibly even earlier traces from the Silurian. Insects have been prominent members of the fossil record ever since, with most prominent major groups having been preserved from late Paleozoic or early Mesozoic formations (200–250 million years ago). A summary of fossil insects is given by Kukalová-Peck (1991).

Major Divisions

Insects and their relatives (together referred to as the Hexapoda) are arthropods, with a chitinous exoskeleton and jointed appendages. They grow by molting, periodically shedding their exoskeleton to allow a new larger body to expand and harden. The closest arthropod relatives to the hexapods are still unknown but probably include some or all of the myriapods (centipedes and millipedes).

The insects formerly included all groups currently classified as Hexapoda, but recently authors have separated the Collembola (springtails) and Protura into a separate group called

Ellipura or Parainsecta (Table 1). The Diplura are placed either within the Insecta or in a separate order of uncertain affinity. All are soft-bodied hexapods usually found in soil or decaying organic material. Most are small, 1 to 5 mm in length, but some Diplura are much larger. The Collembola is the most species-rich group and the one most commonly encountered, as they are often enormously abundant in soil, compost, under rocks, in damp places, and even on the surface of water or snow.

The “true” insects are defined by characters of the structure and musculature of the antenna, among others. There are two relatively primitive groups, the jumping bristletails (Archaeognatha) and the bristletails or silverfish (Thysanura). Both are elongate, wingless creatures with a long, segmented, median “tail” and two shorter, but still prominent cerci. Both groups are scavengers, feeding on vegetable and sometimes animal debris.

The appearance of wings marks the Pterygota. The origin of wings and flight in insects has been controversial, with a number of theories put forward. Most now agree that wings are formed from a movable part of the leg, with its attendant corollary that the protowings were formed in aquatic insects, possibly used for ventilating gills and even for locomotion in water. Extant insects have wings on only the mesothorax and metathorax (the second and third thoracic segments), but fossils exist for which there are also prothoracic wings or wing precursors.

Also unlike the more primitive insects, pterygote insects have hemimetabolus development. The immature stages, often called nymphs, after molting several times, undergo a final molt that produces fully winged, sexually mature adults (except in the Ephemeroptera, which are unique in having a second adult molt; discussed later). More primitive hexapods are ametabolus, with gradual growth through several molts until the sexually mature adult stage, which differs relatively little from the immature forms, is reached.

The most primitive winged insects are sometimes joined in a group called Paleoptera and include the extant orders Ephemeroptera and Odonata. Unlike their more advanced relatives, the neopterans, paleopterans cannot fold their wings down against the body. Both extant orders of Paleoptera have aquatic larvae, but they differ markedly in other aspects of their life histories. Mayflies are generally herbivores, scraping algae and diatoms from objects in the water. When mature,

Table 1 Major divisions of extant insects, simplified

<i>Superclass Hexapoda</i>	
CLASS ELLIPURA (= PARAINSECTA)	
Order Collembola (springtails)	6000
Order Protura	500
CLASS DIPLURA	
Order Diplura	800
CLASS INSECTA	
Primitive insect groups	
Order Archaeognatha (jumping bristletails)	350
Order Thysanura (bristletails, silverfish)	350
Pterygota (winged insects)	
Order Ephemeroptera (mayflies)	2200
Order Odonata (dragonflies and damselflies)	5000
Neoptera (advanced pterygotes)	
Order Plecoptera (stoneflies)	2000
Order Blattodea (cockroaches)	4000
Order Isoptera (termites)	2300
Order Mantodea (mantids)	1800
Order Grylloblattodea (ice crawlers)	25
Order Dermaptera (earwigs)	1800
Order Orthoptera (grasshoppers, crickets, katydids)	20,000
Order Phasmatodea (walkingsticks)	2500
Order Embioptera (webspinners)	200
Order Zoraptera	30
Order Psocoptera (bark and book lice)	3000
Order Phthiraptera (lice)	3000
Order Hemiptera (including Homoptera; true bugs)	98,000
Order Thysanoptera (thrips)	4500
Endopterygota (= Holometabola)	
Order Coleoptera (beetles)	350,000
Order Megaloptera (alder flies, dobsonflies)	300
Order Raphidioptera (snakeflies)	175
Order Neuroptera (lacewings, antlions and others)	5000
Order Mecoptera (scorpionflies)	500
Order Siphonaptera (fleas)	2400
Order Strepsiptera (twisted-winged parasites)	500
Order Diptera (flies)	120,000
Order Lepidoptera (butterflies and moths)	160,000
Order Trichoptera (caddisflies)	7000
Order Hymenoptera (sawflies, ants, bees and wasps)	120,000

Important subdivisions are in bold. A detailed classification can be found in Kristensen (1991, *Insects of Australia*, Vol. 1). Approximate number of described species from various sources.

they emerge from the water in an intermediate, winged stage called the subimago, which lasts only a short time. They molt once more and emerge as winged adults, ready to mate, and die soon thereafter. Dragonflies and damselflies, in contrast, have highly predaceous larvae. There is no subimago stage, as the adults emerge directly and begin relatively long lives as predators of smaller insects. Dragonflies in particular are strong fliers that can travel great distances from water when in search of prey.

The Neoptera are defined by the ability to swivel and fold the wings back at rest. The functional significance of such a modification is obvious—it allows the insect the opportunity to slip into small places to hide from predators and seek food. It has also opened the path to using the wings as protective structures when not in flight, and the forewings of many groups have become hardened or thickened. This is especially evident in the beetles, whose hardened forewings are largely

useless for locomotion and are held out of the way during flight.

The relationships among the more primitive Neoptera are not well resolved. One particularly enigmatic group are the stoneflies (Plecoptera), whose aquatic lifestyle is reminiscent of the paleopterans. The larvae live in clear, cool streams or lakes, where they are herbivores or predators. The adults are weaker fliers than Odonata but longer lived than Ephemeroptera, and they feed on algae, decaying vegetation, or detritus.

The Blattodea, Isoptera, and Mantodea are terrestrial insects sometimes unified in a group called Dictyoptera. Their lifestyles are extremely divergent, however. Cockroaches are flattened, usually cryptic and nocturnal scavengers. They vary in shape and size from small, delicate species a few millimeters in length to large, bulky forms 6 cm long. Most are cryptically colored, but some are mimics of apparently distasteful fireflies (Coleoptera: Lampyridae).

Isoptera are termites, the only eusocial group of insects outside of the Hymenoptera. All species feed on cellulose from wood, leaves, and plant debris that is digested in their gut by a symbiotic microbial fauna of flagellate protozoans or spirochaete bacteria. Some species also culture gardens of fungi in their droppings; the fungi are then consumed and their enzymes aid in digestion. Termites have a number of castes, with most individuals in a colony being soft-bodied workers, along with a lesser number of soldiers and a single queen and king. Nests can be in the ground, in rotting wood or in carton nests built on trees or other structures. Ground-nesting species often build prominent mounds that in some species can reach a few meters in height. Although they appear defenseless, termites have a wide variety of chemical and structural modifications that allow them to resist attack by predators, especially ants.

The praying mantids, Order Mantodea, are voracious predators. They have modified, spiny, raptorial forelegs that grasp and crush their prey, usually other insects but sometimes even small vertebrates. They have no venom or other mechanism for killing their prey other than by eating them. Most mantids are green or brown in color, camouflaging them from attack by predators and detection by their prey. Some are flattened and specifically colored to resemble leaves or petals of flowers.

Unlike the well-known cockroaches, termites, and mantids of the Dictyoptera, the grylloblattids are poorly known and only relatively recently recognized as a separate order. They are found in cool climates, usually at high elevations, in the northern hemisphere living mostly under rocks or in caves. In the spring and summer they can forage on the snow surface, feeding on dead insects and plant material. Ice crawlers lack wings, which they have secondarily lost probably as an adaptation to their cryptic lifestyle.

Earwigs, order Dermaptera, are a distinctive group of insects that have a pair of forceps-like appendages at the posterior apex of the abdomen. Wings are absent in some species, and when present are modified, such that the forewings are shortened and hardened and the hindwings are extensively folded, exposing most of the abdomen. Most species are omnivorous, predatory, or herbivorous and are nocturnal. Usually they are encountered when searching through leaf litter, under rocks, in rotten logs, or in any other hidden crevice.

A much larger group is the Order Orthoptera, the familiar grasshoppers, crickets, and katydids. Most of these have notably enlarged hind legs, used to jump great distances or launch the insects in flight to escape predators. Many katydids are masters of camouflage, with green, leaf-like wings bearing markings that resemble leaf veins, fungal infections, and even insect feeding damage. Other orthopterans are equally cryptically colored, a testimony to the relentless selective pressure exerted by sharp-eyed bird predators. Some grasshoppers and katydids are strong fliers, whereas crickets are usually much more likely to stay on the ground. Most male Orthoptera produce sound to attract mates, and the calls of katydids and crickets are an integral part of the evening chorus in warmer parts (or seasons) of the world. Plants are the food of most species, although there are some predators as well.

Like the Orthoptera, the walkingsticks (Order Phasmodea) are masters of concealment. With their long, stick-like bodies covered in warts, bumps, and spines, walkingsticks can virtually disappear in the appropriate background. One family, whose species are flattened but still extremely well camouflaged, is more appropriately referred to as the leaf insects. All feed on leaves of plants.

The webspinners of the Order Embioptera (webspinners) are an unusual group of small insects that live in silk galleries of their own production. They are narrow bodied, wingless (except for some males), and have the first tarsal segment swollen and filled with silk glands. The galleries they spin are under bark, beneath stones, or in the open in more humid regions; from them they feed on vegetable debris, rotten wood, moss, or lichens.

The Zoraptera are probably the least well known group of insects. They are nondescript, small insects, a few millimeters long, white or pigmented, usually wingless, and with or without eyes. Their life history is little known, although they may be fungus feeders.

A much more commonly seen, but still relatively obscure group are the Psocoptera, the bark and book lice. These small insects, under 1 cm in length, have large, globular heads, rounded bodies, and may or may not bear two pairs of wings. They live on plants, on bark, in leaf litter, or sometimes in human habitations; their food is plant, fungus, and dead insect debris.

Possibly related to some members of the Psocoptera, the Phthiraptera or lice are specialized ectoparasites of mammals and birds. Some species, such as the chewing lice, feed on skin, hair, or feathers, whereas others, such as the sucking lice, suck blood from their hosts. All are small, wingless, flattened insects found only on their hosts.

Outside of the Endopterygota (discussed later) there is only one truly large order of insects: the Hemiptera. This assemblage, in the broad sense, includes groups sometimes named the Heteroptera, or true bugs, and the Homoptera, the cicadas, leaf-, tree-, and planthoppers, aphids, whiteflies, scales, and others. All have distinctively modified mouthparts that are in the form of a piercing-sucking beak that they use to obtain food. Predatory species pierce their prey, usually other insects, injecting digestive enzymes to kill and begin the process of digestion. Predation is restricted to some heteropterans; a few also feed on vertebrate blood. Most Hemiptera are plant feeders, including the majority of the heteropterans and all the

homopterans. Most species are terrestrial, although some heteropterans are aquatic. Some homopterans, especially scales and aphids, produce honeydew, as sweet excretion drips down onto leaves and becomes a major source of food for other insects such as flies and wasps. Some are attended by ants, who harvest honeydew and protect the homopterans from predators and parasitoids.

The thrips, Order Thysanoptera, are another unusual order of insects. They are small, slender-bodied, with or without slender, fringed wings. The last tarsal segment of the legs have an inflatable bladder used to improve the grip on the substrate. The mouthparts are asymmetrical, of the piercing-sucking form, used to feed on debris, fungi, or plants. Thysanopterans also have an unusual form of development in which there are two or three pupa-like stages, similar to the pupal stage of holometabolous insects, but which were independently evolved. At least one tropical species has developed a degree of sociality.

The major group of insects, accounting for about 80% of the species, is the Endopterygota, or Holometabola, two names that refer to different aspects of these insects. Endopterygota refers to the development of the wings from imaginal disks of tissue within the pupa of the immature insect, in contrast to the gradual, external development in less derived insects. Holometabola refers to the development of individual insects through a complete metamorphosis, through egg, larva, pupa, and adult stages. The larva is transformed to an often strikingly different adult through the pupal stage, in which the body tissues are almost completely broken down and then reorganized into adult structures. Imaginal disks, sections of tissue sequestered and formed in the larval stage, are retained in the pupa and are the basis of many of the adult structures, such as gonads, legs, and wings. The almost complete separation of the structure of larval and adult insects allows the holometabolous insects to be extremely specialized in each stage: the larva for feeding and the adult for mating and dispersal. This specialization increases the efficiency of each stage and probably results in the incredible success of holometabolous insects.

Within the Endopterygota, there are four orders that are immensely large and successful: the Coleoptera, Diptera, Lepidoptera, and Hymenoptera. Any one of these megadiversity groups alone is among the largest assemblages of organisms in existence, outnumbering any other group except plants. Together, these four insect orders constitute about 40% of all described species of life on earth.

The most successful order of insects in terms of species number is the Coleoptera or beetles. They are the largest group of organisms in the world, even out-numbering plants. The mesothoracic (first) pair of wings of the beetles are greatly strengthened and hardened, such that they are of little or no use in flight but are superb shields when held over the vulnerable abdomen. These hardened forewings, called elytra, are usually held flush over the back of the beetle, making it slippery and difficult to grasp, as well as hard and difficult to crush. In many groups, the overall body form is solid, flattened, and compact, allowing beetles to hide easily, penetrate cryptic habitats, and even to burrow extensively in soil. Although some beetles have secondarily evolved softened or even greatly reduced elytra, there is no doubt that

this modification has allowed beetles to become the pre-eminent form of insect life on the planet. Primarily a group that is prevalent in warm climates, beetles become relatively less diverse at higher latitudes, but within their range they perform a number of roles, from scavenging, predation, and herbivory to endo- and ectoparasitism. Many species of beetles can be found under stones, in rotting logs, under bark, in freshwater, in fungi, in leaf litter, and on the foliage of plants. Some beetles found on flowers are mimics of bees and wasps, and some beetles found in army ant colonies resemble their hosts to an amazing degree. There are species of rove beetles found in termite nests that carry a passable model of a termite, formed by extensions of their abdomens, over their heads.

There are three orders of insects that are related to beetles but that do not share their same degree of success: the Megaloptera (alder flies, dobsonflies), Raphidioptera (snakeflies), and Neuroptera (lacewings, antlions, and others). The larvae of megalopterans are predatory and aquatic, usually living in clear, running water. The adults are medium to large-sized insects, some of which have enormously enlarged mandibles. In contrast, the larvae of snakeflies are terrestrial, living on the ground in rotting wood or leaf litter and feeding on smaller insects. Adults have a greatly elongated prothorax, giving them a snakelike appearance. Neuropterans are more diverse, with a number of elaborate or bizarre forms intermingled with the more normal-looking lacewings and the damselfly-like antlions and owlflies. All are relatively soft-bodied, with large wings bearing an elaborately reticulate wing venation. Some adults are known to be predatory, as are most of the immatures. The immatures of antlions dig conical pits into which prey fall and are grabbed by the waiting larva. Lacewing larvae are predatory on aphids and other soft-bodied insects found on foliage.

Another large assemblage of holometabolous orders includes the Mecoptera (scorpionflies), Siphonaptera (fleas), Strepsiptera (twisted-winged parasites), and Diptera (flies). The relationships among these orders is in a state of flux, with molecular data giving some indication that fleas are highly modified scorpionflies and that the Strepsiptera, long associated with the Coleoptera, are actually the closest relatives to the Diptera. Previously, some subdivision of the Mecoptera was thought to be most closely related to Diptera; whatever the situation, the monophyly of the scorpionflies relative to some other groups is seriously in question.

Scorpionflies are a relatively small group of insects, so-named because the male genitalia resemble the stinger of a scorpion. Most are terrestrial; the larvae are scavengers and the adults scavengers or predators on small insects. Adults and larvae of the unusual, brachypterous Boreidae feed on mosses, whereas the adults of one genus of Panorpididae are herbivorous. One family, Nannochoristidae, has aquatic immatures that feed on larval chironomid midges. Some species have elaborate courtship behaviors involving nuptial gifts of dead insects to the female.

Fleas are highly modified, laterally flattened, wingless blood feeders on birds and mammals. Usually they are found in the nests or other areas frequented by their hosts. The larvae are usually free living, feeding on organic detritus and blood from droppings of the adults, although some are obligate

ectoparasites. Adults are extremely laterally flattened, allowing them to travel smoothly between the hairs or feathers of their hosts, and often have backwards-pointing combs of spines that makes them difficult to remove. They have strongly developed jumping legs that allow them leap to and from their hosts.

Strepsiptera are extremely unusual parasitoids of other insects. The adults are highly sexually dimorphic, with the males being free-living, winged insects, whereas the females in all but one family are endoparasitoids—wingless, legless, and with only vestigial eyes and appendages of the head. The female body extrudes from the body wall of the host, emitting pheromones to attract males that copulate with the special openings (external genitalia being absent). The larvae are hypermetamorphic, with active, host-seeking first instars that, upon encountering and infecting a host, molt to a legless, relatively inactive form.

As one of the megadiversity groups described earlier, Diptera are found nearly everywhere. Their distinctive innovation has been the reduction of the metathoracic wings to a pair of knoblike halteres that act as gyroscopes in flight. This modification has increased their maneuverability and allowed Diptera to become unparalleled masters of aerial locomotion. Although some adult flies require extensive protein meals to mature eggs and power flight, most of the feeding is done by larvae, which can be predators, scavengers, herbivores, parasitoids and even true parasites. Free-living Diptera larvae are found in soil, rotting vegetation, feeding on and in plants, and sometimes exposed on vegetation. Aquatic forms are found in the silt or sand underlying the body of water (sometimes interstitially), on the surface of rocks, logs, or vegetation, or in the water column. Parasitoids attack mostly other arthropods, but some endoparasites attack mammals.

The orders Lepidoptera (butterflies and moths) and Trichoptera (caddisflies) are close relatives. The lesser of the two—the caddisflies—have aquatic larvae that are found in nearly every type of freshwater environment. Most construct cases or shelters from plant particles, twigs, stones, or sand grains tied together with silk. Some also construct nets to capture debris for food, whereas others are predatory, attacking other aquatic insects. The adults are slender, mothlike insects, often with long, thin antennae.

The Lepidoptera are among the best-known insects, especially the colorful, diurnal group called butterflies. Most of the diversity of the group, however, is in the nocturnal, often drably colored moths, which constitute about 80% of the species of Lepidoptera. The larvae are usually called caterpillars and are best known as voracious feeders on plants. Larval feeding takes place on the surface of the plant or within it (as in leaf miners and stem borers), and almost every plant part—leaves, stems, roots, flowers, and seeds—can be affected. Some species are also predatory and some feed on animal material, such as wool, but almost all species are phytophagous. Adults of most families have mouthparts that are modified to form a long, coiled tube that is used for taking up liquids, usually nectar from flowers. Many adult and larval Lepidoptera are cryptically colored to avoid detection by predators, whereas others are brightly colored to warn of toxic chemicals sequestered in their bodies. Some adults engage in long-distance migrations.

The final large group is the Hymenoptera, the sawflies, ants, bees, and wasps. Like the Diptera, the Hymenoptera have become extremely adept fliers, but have done so by joining the fore- and hindwings with a row of tiny hooks (hamuli) to produce a single functional pair of wings. The most primitive families are phytophagous, but from within these groups have arisen a great diversity of parasitoids, predators, and plant feeders. The parasitoids include some of the smallest known insects, which attack the eggs of their much larger hosts (such as Lepidoptera). Other parasitoids attack a diversity of immature insects, especially those of other holometabolous groups, and develop as endo- or ectoparasitoids. Some are obligatory hyperparasitoids—parasitoids of parasitoids; others oviposit in plant tissue and induce the formation of plant galls, in which the larvae feed. The predatory Hymenoptera attack a wide range of hosts, especially other arthropods, which they often subdue but do not kill with a venomous sting. Larvae of these species have a supply of fresh food to consume when they hatch from an egg laid on the paralyzed prey. Most species hide their prey in some sort of burrow or nest to prevent its being taken by other insects or scavenging animals. Some of these provisioning wasps have moved on to pollen and nectar as food, as in bees. Sociality has evolved a number of times in the Hymenoptera, with the largest and most complex colonies formed by ants and bees.

Conclusion

As this brief survey shows, the largest, most diverse and arguably most successful groups of insects are those that have

undergone three major innovations: (a) the development of wings, (b) the ability to fold wings over the body, and (c) the division of the life history into four major stages. Further outstanding success was found in those species that had hardened forewings (beetles), those that transferred the responsibility of flight to a single pair of wings (Diptera), those that extensively exploited flowering plants (Lepidoptera), and those that combined a single functional wing complex with a number of other traits (such as haplodiploidy) that produced the ants, bees, and wasps (Hymenoptera).

Glossary

Benthic At or on the bottom of streams, lakes, or riverbeds.

Decomposition The breakdown of organic matter such as dead plants and algae to release carbon and nutrients.

Endemic species A species that is unique to a particular locality.

Exotic species A species that has been introduced to an area outside of its native range.

Groundwater A “reservoir” of water residing below ground in saturated soils and beneath geologic formations.

Larvae Early stages in the development of an organism; for invertebrates, often morphologically quite distinct from the adult.

Local species richness Number of species found at a local site; distinguished from regional or global species richness that “sums” the number of species across a number of individual sites.

Planktonic Organisms that reside in the water column.

Watershed A geographical region in which water drains into common water bodies.

Introduction

Water is the most abundant substance on earth and is essential for all of life. It is critical to the world’s climate, to the cycling of nutrients, and is a habitat for much of the earth’s biodiversity. Fresh water links the land and oceans *via* groundwater and riverine flow. While invisible to the human eye, groundwaters represent a substantial portion of the fresh waters (approximately 30%) acting not only as the most important reservoir of fresh water on the earth, but also as a home to many unique fauna. Lakes and reservoirs are also important stores of fresh water and harbor several groups of extremely abundant invertebrates. Running waters and wetlands are known to be havens for diverse assemblages of invertebrates, many of whom are important in ecological processes that ensure clean water. The amount and timing of

water inputs to many freshwater systems worldwide is changing rapidly with growing human demands for freshwater resources, exacerbated by climate change. Since many invertebrates require specific habitats and flood regimes, their abundance and diversity in many parts of the world are at risk because habitats are being lost and natural flow regimes altered at astounding rates. Also contributing to the recent declines in freshwater invertebrates are, poor water quality and the introduction of exotic species that have led to the extinction of native species, especially bivalves and crayfish.

Major Freshwater Habitats

The major freshwater habitats include running waters (streams and rivers), standing or semistanding waters (reservoirs, lakes, ponds, wetlands), and groundwater (**Figure 1**). Most of the

Figure 1 Schematic illustration of major freshwater habitats. Note all water bodies, including lakes, streams and rivers, wetlands, and the oceans, are connected *via* the groundwaters.

35 million cubic kilometers of fresh water on the earth ($\approx 69\%$) exists in the form of polar ice. Of the remaining fresh water, a huge volume exists out of sight as groundwater (Table 1). Lakes, streams, and wetlands represent less total water volume but are biologically rich hot spots for abundant and diverse assemblages of invertebrates. Together, the freshwater bodies form a continuous “pipeline” that links the atmosphere, land, and the oceans. Rainwater is intercepted by vegetation on land, percolates through the soils into groundwaters, and then moves into wetlands, lakes, and streams before it eventually reaches the oceans (Figure 1). Since groundwater directly or indirectly “feeds” all other water bodies on earth, maintenance of adequate quantities of high-quality water in this underground reservoir is a high priority worldwide.

Major Groups and Their Lifestyles

A disproportionate number of species live in fresh waters compared to marine systems: oceans comprise 70% of the earth’s surface while inland waters make up about 1%. Despite this, about 10% of all animal species alive today live in fresh water. The majority of the freshwater animal species are invertebrates. More than 107,000 freshwater invertebrate species have been described but many more remain undiscovered – new species and genera are found every year (Balian *et al.*, 2008). Freshwater habitats have representatives from most taxonomic groups with the insects being particularly speciose (Table 2). The freshwater insects are also quite notable for the large number whose lifestyle changes with age: many have aquatic larval stages but flying adults. This is in contrast to freshwater mollusks and crustaceans that complete their life cycles in water either as members of the plankton or benthos.

Life cycles of freshwater invertebrates can be quite complex with multiple, morphologically distinct stages (Thorpe and Covich, 2010) (Figure 2). For example, among the freshwater bivalves, some are hermaphroditic while others have separate sexes; some brood their eggs and then release small clams; however, many release larvae into the water. Zebra mussels produce a planktonic larval stage (a veliger larva), while some of the most common freshwater native bivalves have unique parasitic larvae (glochidia larvae) that attach to the skin, scales, or gills of fish. The host fish disperses the attached glochidium larvae, prior to the detachment of larvae and their metamorphosis into adult bivalves. This dispersal phase may be very important to the long-term survival of bivalves particularly in freshwater bodies that are being stressed.

Damselflies and dragonflies provide other examples of complex life cycles typical of many freshwater invertebrates.

These insects have flying adults that live weeks to months and lay eggs on aquatic vegetation or other substrates. The eggs hatch within 12–30 days, or they can remain viable in an unhatched state (diapause) if there is a drought. Small larval stages (sometimes called nymphs) hatch from the eggs and then molt multiple times (10–16) before crawling up vegetation and “emerging” as flying adults. The presence of an intact riparian zone with a diversity of native plants promotes population persistence of insects.

Number of Freshwater Invertebrate Species

The number of freshwater invertebrates varies considerably between lakes, running waters, groundwaters, and wetlands. Since the number of species varies vastly from locale to locale as a function of many complex factors, estimates of species richness should be taken as only approximations. Additionally, freshwater invertebrate diversity at any one time may be moderate while accumulated diversity over time may be very high. For example, there may be dramatic declines in invertebrate diversity in many streams during the flood season but high levels of diversity across the entire year. Similarly, temporary wetlands may have much higher total diversity over time than permanent wetlands even though the snapshot diversity in a temporary wetland may be considerably lower.

Many freshwater wetlands are extremely speciose habitats (e.g., up to 2000 invertebrate species at a locale), followed by lakes and streams (80–1400 species of invertebrates typically found at a locale), and then groundwaters (0–150 at a locale). In all these habitats, insects are by far the most speciose group with local species richness levels of 50–500 and global richness levels of nearly 76,000 species. Crustaceans may attain local species richness values of up to 150 and global richness values of 12,000 species; water mites up to 75 species locally and 6000 species globally; annelids up to 50 species locally and nearly 2000 species globally; nematodes and rotifers up to 500 species locally and 6000 species globally; and mollusks up to 100 species locally and 5000 globally.

Some freshwater habitats are hot spots of endemism harboring many unique fauna. For example, ancient lakes such as Lake Baikal in Siberia have rich abundance of endemic fauna, especially for those species that live all of their lives in fresh water and have a poor capacity for dispersal. For one group of crustacean amphipods, the gammarids, this lake has the highest level of endemism in the world (41 genera, of which 38 are endemic). Other lakes that harbor highly endemic invertebrate faunas include the African rift lakes of Lake

Subclass Acari: Hydrachnidia	Water mites	GW, RW, SW	B, P	6007
Class Insecta				75,000
O. Ephemeroptera	Mayfly larvae	RW, SW	B	3046
O. Odonata	Dragonfly and damselfly larvae	RW, SW	B	5680
O. Plecoptera	Stonefly larvae	RW, SW	B	3497
O. Heteroptera	True bugs	RW, SW	B, P	4801
O. Trichoptera	Caddisfly larvae	RW, SW	B	11,532
O. Megaloptera	Dobsonfly larvae, fishflies, hellgrammites	RW, SW	B	328
O. Neuroptera	Spongillaflies	RW	B	118
O. Coleoptera	Water beetles	RW, SW	B	12,604
O. Diptera	Fly larvae (e.g., midges, craneflies, blackflies, mosquitoes)	GW, RW, SW	B, P	32,281
O. Lepidoptera	Butterfly and moth larvae (caterpillars)	RW, SW	B	737

Note: Some groups are more common in running waters (RW), such as streams and rivers while others are more common in standing or semistanding water (SW) bodies (lakes, streams, wetlands) or groundwater (GW). Some are primarily benthic (B), existing in or on the bottom of lake, stream, river sediments, or on aquatic vegetation, while others maintain a water column existence as members of the plankton or pelagic fauna (P). Estimates of diversity are derived from the Freshwater Animal Diversity Assessment.

Tanganyika and Lake Nyasa, Lake Titacaca in Peru, and Lake Lanao in the Philippines.

Dominant Taxonomic Groups across Freshwater Habitats

In running waters, the dominant invertebrate groups vary considerably depending on the type of bottom substrate (e.g., mud, cobble/boulder), the flow, and available sources of

organic matter (Allan, 1995) (Figure 3). In rough-bottom creeks and swift-flowing streams, invertebrates live primarily on or beneath pebbles and boulders on the bottom and include many species of insects, crustaceans, and mollusks. In deep riverine areas, fine sediments predominate, the near-bed water flows more slowly, and planktonic invertebrates become common in the water column. In the soft sediments, burrowing insect larvae, bivalves, and worms are common as long as oxygen is present (Palmer *et al.*, 1997).

Figure 2 Example of a complex life cycle for a freshwater invertebrate. Many freshwater bivalves are benthic yet produce larvae that are released into the water column. These develop into small glochidium larvae that attach to a fish host. After some time, the larvae metamorphose into small bivalves, detach, and take on a benthic existence.

Benthic species can be classified according to how they feed, also known as functional feeding groups (Merritt and Cummins, 1996). “Shredders” are adapted to feed on decomposing plant material that has fallen into the stream. “Collector-gatherers” filter or gather particulate organic matter or drifting organisms from the water column. In streams where more sunlight reaches the bottom, animals known as “scrapers” feed on the algae that readily grows on rocks and sides of the channel.

In lakes and ponds, the most common invertebrates include crustaceans, rotifers, insects, and oligochaetes; however, taxonomic composition varies dramatically depending on the size of the lake and the position within the lake (Hutchinson, 1967/1993) (Figure 4). Benthic invertebrates are particularly abundant and speciose along the lake margins but generally are less numerous in the deeper parts of the lakes where oxygen may be limiting and habitat diversity is much lower. However, a few species that are tolerant of silt and low oxygen such as oligochaetes, midge larvae, and nematodes may be extremely abundant in the deeper part of lakes. In the water column, abundant planktonic invertebrate communities thrive by feeding on phytoplankton, but these invertebrate assemblages typically are dominated by just a few taxonomic groups such as rotifers, copepods, and cladocerans.

In the groundwater, crustaceans, rotifers, and nematodes are very common, and many of these are adapted for adept movement among rocks and particles of sand (Gibert *et al.*, 1994). In some parts of the world, insect larvae are common in the groundwater and may be found great distances away from the nearest surface water. Important crustacean groups in groundwater include copepods and less commonly amphipods, ostracods, isopods, and decapods. Many of these live in caves and sinkholes. Groundwater invertebrates are particularly interesting because of the unique adaptations many of them possess for life in dark, isolated habitats where food may be scarce. For example, the Edwards Aquifer in Texas harbors a unique fauna of 22 species including 10 amphipod species. Many of these species have reduced (or no) eyes, body pigmentation, and body size, low metabolic rates, and an enhanced sensitivity to touch.

In freshwater wetlands, the number of habitats and types of food sources for invertebrates are vast. The soft sediments are filled with burrowing nematodes, oligochaetes, midge larvae (a dipteran insect), and mites. Some invertebrates feed on or around the roots of vegetation, while others burrow through the sediments consuming bacteria, fungi, or other invertebrates. In the overlying water, crustaceans, rotifers, and insect larvae (e.g., mosquito larvae) are common and feed on phytoplankton or invertebrate prey. The stems of emergent and submerged vegetation in wetlands are

Figure 3 Schematic illustrating the River Continuum Concept (RCC) that proposed a relationship between stream size (small upland streams to large downstream rivers), flow and bottom substrate, and type of macroinvertebrate groups likely to dominate. In the smallest streams, large inputs of leaves and wood along with benthic algae are particularly important sources of food for invertebrates. These invertebrates “shred” the leaf material into finer particles and thus facilitate its further breakdown by fungi and bacteria. Further downstream, where sunlight penetrates the water and flow is reduced, algae are also important sources of food and many invertebrates “scrape” the algae from rock surfaces. In the very open riverine areas, plankton may be an important food source and many of the benthic invertebrates burrow into the fine sediments. Modified from Vannote RL, Minshall GW, Cummins KW, Sedell JR, and Gushing E (1980) The river continuum concept. *Canadian Journal of Fisheries and Aquatic Sciences* 37: 130–137.

typically crawling with diverse assemblages of crustaceans, mollusks, and insects. Small shrimp-like crustaceans (amphipods) may reach very high levels of abundance on aquatic vegetation. Water beetles, odonates (dragonflies and damselflies), and waterbugs (water boatmen, waterstriders, and backswimmers) are commonly the top predators.

Global Patterns in Freshwater Biodiversity

Knowledge of lineage histories is very important because regional patterns of distribution of species are often a reflection of distinctly different evolutionary histories. Adaptations to specific climates and habitat characteristics influence speciation and the ability of an organism that evolved under one set of circumstance to move broadly among different geographic areas. Terrestrial and marine biologists generally have found the highest levels of animal and plant diversity in the tropics with lower levels in temperate and polar regions. This is not necessarily the case for freshwater invertebrates. Species richness for freshwater invertebrates is related in very complex

ways to latitude and elevation, and global patterns of diversity are not straightforward for this group.

There have been far fewer surveys of freshwater invertebrates in the tropics than in temperate regions; however, those to date suggest that biodiversity in fresh water is not typically higher in low latitude, tropical habitats. For example, in North America, bivalves and crayfish appear to be the most diverse in temperate zones (about 260 native bivalves and 320 species of crayfish). Temperate zones have a wealth of crayfish species, but tropical fresh waters have a richer shrimp and freshwater crab fauna. Insects, mayflies, and stoneflies are more diverse in temperate latitudes than in the tropics, whereas dragonflies, waterbugs, and water beetles are much more diverse in the tropics.

Factors Influencing Biodiversity in Fresh Waters

Scientists have devoted their lifetimes to the study of what determines the number of species in a given habitat type or

Figure 4 Representative invertebrates from different zones within a typical lake: (1) pelagic zooplankton; (2) surface; (3) littoral water column; (4) littoral benthos; (5) hypolimnion benthos. Modified from Figure 2.12 in Thorp and Covich (2010), *Ecology and Classification of North American Freshwater Invertebrates*, 3rd edn. New York: Academic Press.

geographic region. These studies have involved thoughtful, systematic observations of patterns of distribution dating back many years (e.g., Robert Pennak's work in many freshwater systems), and more recent experimental studies that have cleverly manipulated some factors believed to influence biodiversity. From such studies, we know that biodiversity in fresh waters is determined by both historical (e.g., age of a lineage, evolutionary constraints) and contemporary factors (e.g., habitat heterogeneity, predator-prey interactions). The relative importance of many factors varies geographically as well as between habitats in the same geographic region.

The Origin of Freshwater Invertebrates

Most freshwater invertebrates are believed to be derived from terrestrial or marine ancestors (Bănărescu, 1990). Representatives from many different groups of marine crustacea (shrimp, copepods, cladocera) may have made the transition from salt water to fresh water through many years of evolution in increasingly brackish (low salinity) water. Success in fresh water required that the animals be able to maintain ionic balance in their body fluids (not gain too much body water), reproduce without the aid of complex tidal currents to carry eggs and larvae, and, in some cases, develop life stages that could withstand freezing or drying. Only certain species could make this transition, so at the phylum level, freshwater biodiversity is more limited than in the oceans. For example, echinoderms (e.g., starfish) did not develop the ability to osmoregulate in fresh water.

Many freshwater invertebrates are secondary aquatic forms that moved, in an evolutionary sense, into fresh waters from the land. The most notable group of secondary invaders is the insects, many of which still have terrestrial adults. Some insect orders, such as the Heteroptera, Coleoptera, and Diptera, have both freshwater species and terrestrial species in abundance. Heteroptera and Diptera also have a few highly specialized marine species. Water mites (Acari) coevolved with insects and many species are parasites on the adult insects. With their coevolutionary links, they are also secondary invaders of fresh waters. Freshwater snails consist of two major groups, the prosobranchs and the pulmonates. Pulmonates have invaded freshwater systems from the land; freshwater forms include the two common and ubiquitous families of pond snails, the Lymnaeidae and Physidae.

Habitat Age and Isolation

Some freshwater habitats are extremely old and have been isolated for very long periods of time. These habitats have a high degree of endemism. For example, Lake Baikal in Siberia is extremely old and has many species that are found nowhere else in the world. Such "hot spots" of unique species are considered valuable for conservation purposes and for use as a "natural laboratory" for the study of invertebrate evolution.

For those ancient freshwater bodies that are highly isolated, resident fauna may be at a high risk of extinction. If a freshwater species is highly specialized for conditions at a particular site and conditions change, it may be unable to

survive. Geographic or habitat remoteness is not the only factor promoting isolation of freshwater invertebrates. Some fauna are isolated because they have very limited dispersal abilities. For example, many groundwater and deep-streambed dwelling species are very poor swimmers and lack dispersal stages. Thus local biodiversity may be low even though regional biodiversity is much higher – species from the large-scale regional “pool” of invertebrates (e.g., all rivers in a geographic region) may not be able to move between all watersheds. In general, ecologists assume that local species diversity represents a subset of the regional pool of species and the size of this subset depends greatly on both dispersal abilities of fauna and geographic barriers to dispersal.

Habitat Heterogeneity and Disturbance

A central tenet of ecological theory is that the greater the number and types of habitats, greater is the species diversity. Put simply, different types of organisms with different niche requirements can exist in areas that are heterogeneous over space and time. In freshwater ecosystems, spatial heterogeneity (and species diversity) is enhanced by anything that leads to a great variety of particle sizes in which benthic organisms can burrow and feed. Similarly, spatial heterogeneity and species diversity of planktonic invertebrates is enhanced by anything that promotes the growth of many types of vegetation because this provides the invertebrates with diverse food types and hiding places from predators.

Environmental variation over time (temporal heterogeneity) is also extremely important as a determinant of species diversity. Variable climate and flow regimes will promote seasonal (or longer) changes in species abundances and may determine whether a species can coexist in a location. Some freshwater invertebrates have evolved life cycles to take advantage of or avoid predictable changes in water level, flood flows, or ice scour. However, when these environmental changes become extreme or highly unpredictable (a “disturbance”), species richness may decline as fauna are unable to evolve coping strategies that keep up with such changes. Many ecologists believe that invertebrate species diversity is greatest when natural disturbances like floods are at intermediate levels with respect to severity or predictability. High levels of disturbance will wipe out most species while low levels of disturbance may favor one or two species to the exclusion of other species that are poorer competitors.

Species Interactions

Predation and competition are well known to influence local species diversity in freshwater ecosystems. For example, many fish predators are highly selective in their feeding and may forage on a single species or suite of species. Thus, predation pressure may reduce species diversity locally, or it actually may promote species diversity if the predator is removing a species that is a competitive dominant. Competitive dominants are species that are so good at garnering resources (space, food, etc.) that other species are unable to coexist with them. The process of competitive exclusion also may be prevented by

disturbances if the disturbance (e.g., a flood or drought) has a disproportionate effect on the competitive dominant.

In freshwater ecosystems, some of the most dramatic examples of the delicate balance that species interactions play in determining biodiversity come from the introduction of exotic species. Many exotic fish have been introduced into lakes throughout the world and have had devastating effects on their invertebrate prey or on other fish that in turn prey on invertebrates. Introduced carp have reduced invertebrate populations in floodplain wetlands. Nonnative trout introduced to streams have depleted populations of native fish and increased trout predation pressure on native invertebrates.

The Role of Invertebrates in Ecological Processes

Healthy freshwater ecosystems are those in which the ecological processes continue unimpeded to ensure that water is clean and the organic matter in a lake, stream, or wetland is not lost or accumulated in excess. Freshwater invertebrates play key roles in these processes. The most important ecological processes in freshwater systems include decomposition of the organic matter; the uptake and transfer of materials such as sediments, nutrients, and contaminants; and production by plants.

Decomposition of Organic Matter and Recycling of Nutrients

Decomposition releases elemental carbon and nutrients (nitrates, phosphates) to the environment with the result that plants and animals that rely on these nutrients thrive. Additionally, decomposition ensures that wastes and dead organic material do not build up in bodies of water. Terrestrially produced leaf and woody litter and dead aquatic vegetation and plankton sink to the bottom of lakes, streams, and wetlands. Once deposited within fresh waters, this organic matter can be broken down directly by bacteria and fungi. Often however, the material first must be altered by invertebrates, which fragment or shred it before ingesting it. The shredding activities of invertebrates are important because smaller fragments of dead leaves and other organic matter are decomposed by microbes much faster than larger pieces. Additionally, through their feeding activities, invertebrates can enhance the abundance and reproduction of the microbes, which further acts to stimulate the rates of decomposition.

The Uptake and Transfer of Materials

Movement of water, sediment, and organic material within and from freshwater systems has a profound effect on global biological, geological, and chemical processes. Freshwater invertebrates may alter the rate at which water flows through sediments. For example, burrowing oligochaetes, nematodes, midge larvae, and crustaceans can increase the rate at which water moves through lake and stream sediments and to nearby groundwaters. Instead of increasing water flow and percolation through sediments, some freshwater invertebrates bind

sediments by producing mucus “biofilms” or dense mats of tubes or filaments that reduce water flow and the movement of sediments. This may act to improve water clarity so that sunlight penetrates deeper and plant production is enhanced. Similarly, water clarity may be enhanced by dense populations of bivalves that filter water as they feed and remove suspended matter. Freshwater invertebrates also may influence the concentration of contaminants in the water or bottom sediments by accumulating the contaminant in their bodies or *via* direct degradation of toxic materials.

Production by Plants

In freshwater ecosystems, the synthesis of organic matter by plants depends on the presence of sunlight and nutrients. Rates of primary production are extremely variable across freshwater ecosystems, ranging from low in poorly lit groundwaters or turbid lakes to quite high in well-lit shallow wetlands. Aquatic herbivores may directly affect plant production as the miffoil weevil, *Euhrychiopsis lecontei*, does in feeding on both northern (*Myriophyllum sibiricum*) and Eurasian (*M. spicatum*) water-milfoils in North American lakes. However, the indirect effects that invertebrates have on plant production are also significant. The availability of nutrients for aquatic vegetation and phytoplankton depends to a greater extent on the decomposition of organic matter in aquatic sediments and the movement of nutrients. Grazing and movement of invertebrates stir up the bottom sediments and mix water, increasing the availability of nutrients to plants and phytoplankton. Furthermore, planktonic invertebrates that graze on phytoplankton excrete forms of phosphorus and nitrogen that are immediately available to further enhance algal growth. Grazing may be particularly important in the removal of senescent algae, thereby increasing light as well as nutrients.

Threats to Freshwater Fauna

The loss of freshwater invertebrate biodiversity because of damage generated by human activities is an immense global problem (Strayer, 2006). A major difficulty in assessing the dimensions of the problem is the poor state of knowledge of freshwater invertebrate taxonomy and distribution and the lack of reliable monitoring to identify loss of diversity. In spite of these problems, it is clear that invertebrate species in some places already have high levels of population decline and extinction. In fact, it has been estimated that over 10,000 freshwater species are already extinct or greatly endangered as a result of human activities.

The major threats to freshwater biota in general, and freshwater invertebrates in particular, are habitat degradation and loss, pollution and reduced water quality, altered hydrologic regimes, and invasion by exotic species. In many situations, the major threats do not act alone but can act synergistically; moreover, they will interact with and possibly be exacerbated by global climate change (Allan, 2004). Thus, for example, streams in agricultural areas may lose their invertebrate fauna due to habitat loss by sedimentation, pollution by pesticides, altered flow regimes due to irrigation, and

the introduction of exotic species, including plants, fish, and invertebrates. Increased variability in the frequency and intensity of rain events as well as rising temperatures may further stress any vulnerable invertebrates remaining. A fifth threat to freshwater fauna is overexploitation. For example, harvesting of the mussel *Margaritifera margaritifera* for pearls has reduced populations by 90%.

Loss and Depletion of Habitat

Humans have damaged water bodies by river channelization and dredging, sand and gravel extraction, wetland drainage, lake and river shore development, dam and barrier construction, water diversion, levee bank construction, and valley fills associated with mountain top mining. Human activities on land can have indirect but significant effects on fresh waters. For example, sedimentation from poor land use, destruction of riparian vegetation, loss of surface runoff, and loss of water by groundwater extraction for irrigation, all can damage fresh waters. Indeed, studies have shown that when just 5–10% of a watershed's area is affected by anthropogenic activities, stream biodiversity and water quality suffer.

Temporary wetlands are common in many regions. They may have surface water only occasionally but when they do, they are very productive and harbor a distinctive invertebrate fauna adapted to survive long dry periods. Unfortunately, in many areas the importance of temporary wetlands as distinctive habitats of high biodiversity value has not been recognized and many of these wetlands have been plowed, drained, and filled in.

Sedimentation of streams and wetlands from erosion can be caused by activities in watersheds such as land clearance, plowing and tillage of soil, road building, and logging. The mass delivery of sand and silt into water bodies can reduce invertebrate diversity and change species composition by filling in pools in streams, wetlands, ponds, and even lakes, burying porous coarse sediments with layers of fine sediments with very low permeability, and covering the aquatic plants. The deep streambed of running waters has a rich and distinctive fauna dependent on the high permeability of gravels and sands. Sedimentation can clog the pores in the streambed reducing water movement and oxygen availability, which leads to the loss of fauna. Many streams that originally had stable, habitat-rich channels, and a rich invertebrate fauna have been damaged when channels were filled by fine shifting sediment that consequently has led to a greatly depleted fauna.

A property vital to the nature of rivers, and essential for maintenance of invertebrate biodiversity, is connectivity – the unimpeded movement of water, longitudinally from source to mouth, and laterally between the channel and its floodplain. Loss of connectivity greatly alters invertebrate species composition and may reduce diversity. Dams on rivers are barriers to longitudinal connectivity because they disrupt the downstream movements of nutrients and organic matter and prevent movement of invertebrates and fish. Levees are barriers to lateral connectivity because they are designed to stop lowland rivers from flooding their floodplains; however, periodic

floodplain inundation is essential for the maintenance of biodiversity of the river system.

Pollution and Reduced Water Quality

Pollutants can enter fresh waters through point sources such as sewage outfalls, or *via* diffuse nonpoint sources such as runoff from agricultural fields. Pollutants in sewage and agricultural runoff include organic matter and nutrients. Organic pollution of rivers usually is released from point sources, and downstream from the point source, dissolved oxygen concentrations may drop greatly. The normally diverse fauna of the river is eliminated and replaced by an abundance of a few species that can tolerate low oxygen levels. As the organic matter is processed, the river may recover further downstream. In lakes contaminated by organic pollution, decomposition of the organic matter and elevation of the nutrient levels also may create low oxygen conditions in the benthic regions so that the normally diverse benthic invertebrate fauna is replaced by species similar, if not identical, to those found in the anoxic sections of organically polluted rivers.

Nutrients such as phosphorus and nitrogen enter fresh waters either from sewage or from diffuse sources, such as agricultural fertilizers. Nutrients may encourage the growth of undesirable algae and may cause algal “blooms” and periods of low oxygen availability, especially in the deeper benthic regions. This process is called cultural eutrophication and is a major problem for lakes in both urbanized and rural areas (Scheffer, 1998). In such lakes, the invertebrate fauna, both planktonic and benthic, is depleted in species diversity, but abundances of a few tolerant species may be very high.

Combustion of fossil fuels can generate sulphur and nitrogen oxides that combine with water to form acids in the atmosphere. Acids dissolved in water vapor can move long distances in the atmosphere before entering water bodies as acid rain. This process is a dramatic example of nonpoint source pollution in which pollutants generated in one region exert their effects on another, often distant, area. Many poorly buffered lakes in Europe and North America have become strongly acidic due to acid rain. In acid lakes (pH < 4.5), some invertebrate groups such as crustaceans and mollusks are eliminated along with gill-breathing insect larvae. The most acid-tolerant taxa appear to be predatory waterbugs.

In many parts of the world, irrigation may reduce river flows and create extensive salinization (salt contamination). Salinization occurs when water evaporates from irrigated fields and leaves behind the salts that were dissolved in the water. The increased salt levels in the soil kill terrestrial vegetation. The concentrated salt can enter rivers and lakes where it eliminates most of the freshwater invertebrates, except for a few tolerant midge larvae and crustaceans. The Aral Sea in Russia was once brackish water and fauna rich. Its freshwater inputs were diverted for irrigation, and it now receives very saline waters from irrigated lands. As a consequence, it has shrunk greatly in size to become a saline sea with a very impoverished fauna.

Many pollutants, such as heavy metals and chlorinated hydrocarbons, are not readily broken down or deactivated.

Once they enter a freshwater system through point or nonpoint sources, they persist and continue to cause damage. Heavy metals, such as zinc, copper, cadmium, and lead, may enter a water body from mining operations and poison the system, thereby eliminating many invertebrate taxa. Unfortunately the contamination may persist for many years, even long after mining operations cease. In Wales (Britain), Australia, and many parts of the US, rivers have remained contaminated 35–90 years after mining ceased and they continue to have a depauperate invertebrate fauna.

Altered Water Regimes

In the past century with the growth in human populations and the rapidly rising demands for water for human consumption, industry, hydropower, and irrigation, there has been an enormous expansion in the number and scale of dams, barges, and diversion works. Dams and their large upstream impoundments break the connectivity of rivers. This disruption has been recognized in situations where valuable fish stocks have been threatened. Fishways, portage schemes, and stocking have been used to reduce threats to fish, but nothing has been done to alleviate the effects on invertebrates. Thus dams may disrupt essential migrations, such as those of shrimps and freshwater crabs in the tropics, and prevent the normal movements of invertebrates down the river.

The waters impounded behind dams may flood valuable habitats – floodplain wetlands, river canyons, even lakes. In Tasmania, Australia, a large dam-created impoundment flooded an entire isolated lake with a remarkably large beach. This lake, Lake Pedder, contained five endemic invertebrate species, four of which appear to have become extinct. Impoundments behind dams may have a greatly depleted littoral (shoreline) fauna due to rapid changes in the water level incurred as a result of dam operations. Drawdown of lake levels to meet hydroelectricity or irrigation can leave many invertebrates stranded. In unimpounded rivers, organic matter and nutrients are transported downstream to be used by downstream invertebrates. This longitudinal transport ceases with impoundment. Water released from dams may come from the deep hypolimnion and consequently may be cold, deoxygenated, and low in organic material – conditions quite unfavorable for riverine invertebrates.

The purposes for which a dam is operated can have direct consequences for downstream invertebrates. Most drastic of all is the simple loss of water. Many dams are water diversion structures that leave the river channel below the dam waterless or with a small minimum flow. In many places, large rivers are left with so little water that they no longer reach the sea. Needless to say, the loss of invertebrates is considerable. Dams may be built and operated to generate hydroelectricity, wherein water levels in the channel below the dam fluctuate greatly and quickly as water is released or suddenly cut off to meet the electricity generation demands. Alternation between flood and drought creates disturbance levels that permit only the hardiest of invertebrates to exist in the channel. Dams operated to store water for irrigation, hold water in the wet season (winter), and release it for irrigation in the dry season. Consequently, the seasonal patterns of flow are reversed, and wet season floods are

greatly diminished. The lack of water in the wet season and high water levels in the dry season disrupt the life cycles of many invertebrates. For many lowland rivers, the effects of greatly diminished floods have been devastating because inundation of the floodplain has been greatly reduced, resulting in a loss of invertebrates that would normally thrive on the floodplain.

Invasion of Exotic Species

Exotic species of plants and animals may reach new localities through deliberate introduction by humans or accidental introduction during transport. The rate of introductions both between and within continents is rising rapidly. The most obvious introductions into freshwater systems have been plants, both aquatic (e.g., water hyacinth) and riparian (e.g., salt cedar), and fish (e.g., carp). Few invertebrates have been introduced deliberately (e.g., opossum shrimp, crayfish), but many, especially crustaceans and mollusks, have been introduced accidentally (e.g., spiny and fishhook water fleas, zebra mussels).

Introduced invertebrates may exert very strong effects on native species. Exotic invertebrates may be vectors for diseases lethal to native species. In Europe, native crayfish stocks have been decimated by the crayfish plague fungus, *Aphanomyces astaci*, which came with the deliberate introduction of North American crayfish. Exotic species may take up habitat space and outcompete local species. Zebra and quagga mussels from the Ponto-Caspian region invaded the Great Lakes, spread rapidly through eastern North America, and have now been detected in reservoirs and lakes in Colorado, Utah, and California. They monopolize habitat space and have greatly reduced native mussels (Strayer *et al.*, 1999). Zebra and quagga mussel populations increase rapidly once introduced to new water bodies and through their immense filtration capacity may greatly reduce planktonic organisms, increasing the clarity of water but reducing the invertebrate diversity.

Introduced aquatic plants, such as water hyacinth and alligator weed, may blanket the surfaces of lakes and rivers. Such blanketing may reduce water quality by causing deoxygenation or by reducing photosynthesis of native plankton and aquatic plants. This, in turn, diminishes food resources for native invertebrates. Introduced riparian plants, such as tamarisk or salt cedar, may cause the loss of habitat for native invertebrates by dominating the stream banks and often by reducing water levels in the channel. Other introduced plants,

such as eucalypts in Spain and Portugal, may produce dead plant material that is not readily consumed by stream invertebrates, thereby causing them to starve.

Many fish are predators of the invertebrates. The introduction of exotic fish may increase predation pressure and deplete native invertebrate populations. Introduced carp have reduced invertebrate populations in floodplain wetlands. In New Zealand, introduced trout in invading streams have depleted or eliminated populations of native fish and native invertebrates. Released from the intense grazing pressure of native invertebrates, algae in such invaded streams proliferate and build up to high levels.

Glossary

Benthic That connected with the bed of the sea or a freshwater lake, river, or stream.

Deep sea The seabed and immediately overlying water covered by seas at least 200 m deep.

Disturbance A biological or physical factor that impacts a population or community by causing death, reduced reproduction, or increased emigration.

Infauna Animals living within sediments.

Invertebrate All animals that lack a backbone (vertebrae)—that is, most of the animal kingdom.

Pelagic That connected with the water column.

Planktonic Organisms of many different phyla that float in and are carried by water masses in the pelagic of the sea or freshwater.

Production The increase in biomass of an individual, population or community as it grows by converting energy-food into biomass.

Physical Characteristics of The Oceans

The world ocean covers more than two-thirds of the surface of the earth and as much as 90% of the habitable volume. It is the largest habitat on earth and about one billion people depend on the oceans for their primary protein needs. Yearly, well over 90 million tons of fish and shellfish are harvested.

Only 10% of the oceans' area could be classed as shallow water and this is mostly located around the continental margins. Seas deeper than 2000 m cover half the earth's surface. The seashore zone, the area covered and exposed by tides, corresponds to the ecological littoral region. Shallow seas make up the sublittoral zone, also called the continental shelf, which ends at the shelf break, usually at around 200 m. The continental slope marks the boundary between the continental and ocean floor crusts. It extends from the shelf break down to about 1500 m, so it roughly corresponds to the ecological bathyal region, 200 m to 2000 m.

The continental slope falls away into the continental rise, which extends down to a depth of about 4500 m. Beyond this is the abyssal plain at depths of between 5000 to 6000 m. The continental rise and the abyssal plain roughly correspond to the ecological abyssal region, 2000 to 6000 m. Other features of the seafloor are rocky seamounts and ridges, which may be of a considerable size, and deep trenches down to 11,000 m or more. Trenches are usually a feature of subduction zones where the seafloor buckles and deepens beneath a continental crust. Deep trenches correspond to the ecological hadal region. The continental rise and abyssal plain tend to be relatively flat. Geological features such as terraces and submarine canyons, however, sculpture the continental slope. Pressure increases down the water column at the rate of one atmosphere per 10 m.

Much of the seafloor is covered in sediments; bare rock is rather rare. Near the coast these sediments are of terrigenous origin and may be coarse (e.g. clay, sands, or pebbles). Terrigenous material may be found down to the continental rise and vast areas of the seafloor consist of clay sediments or, in

productive areas, biogenic oozes mainly from diatoms, radiolarians, and Foraminifera.

The temperature of the water declines rapidly with depth until it stabilizes at about 4 °C, which takes place at approximately 1000 m, depending on latitude. This phenomenon is known as the permanent thermocline. At greater depths, the temperature declines slowly. Water currents are too complex to be discussed here in detail but, broadly speaking, deep water is formed by the sinking of dense, cold saline water in the Antarctic and Arctic. This dense water spreads out across the world ocean, eventually returning to the surface.

In general, marine water is well oxygenated, often at values near saturation. There are areas where rapid seasonal blooms in the upper water column deoxygenate the water leading to oxygen minimum zones. Oxygen concentration falls rapidly with sediment depth, especially in littoral muds and sediments under shallow enclosed seas.

The open ocean or pelagic realm has no obvious boundaries such as the mountain ranges or large water masses (rivers, seas, or oceans) that are so important in driving speciation on land, although to a certain extent the three oceanic basins—Atlantic, Indian, and Pacific—are partially separated by landmasses. The world ocean is essentially a continuum and the most important environmental factors are temperature and salinity, which translate primarily into latitude and depth. However, despite the lack of obvious barriers, speciation has and does occur in the pelagic environment. The geographic species distribution of modern plankton is the product of the geological history of the oceans and continental barriers, limitations of species in adapting to biotic and abiotic environmental factors, and the degree of organism mobility.

The pelagic realm is divided by depth into zones. Light, temperature, and salinity are responsible for the major vertical biodiversity gradients. In the upper 200 m, the epipelagic, sufficient light is available to sustain photosynthetic processes. This is the primary production zone where light and carbon dioxide is converted into carbohydrates, the principle energy (food) source for all open ocean inhabitants. The mesopelagic

Table 1 The division of the pelagic environment into depth zones (measured in meters)

Epipelagic	0	200	The photic zone, primary production
Mesopelagic	200	2000	The realm of diurnally migrating organisms
Bathypelagic	2000	6000	The deep-sea realm, continuous darkness
Abyssopelagic	>	6000	The deep-sea troughs, continuous darkness

**Figure 1** The global distribution of benthic biomass in the world ocean based on the work of the Russian sampling programme of Belyaev and colleagues. This work established that biomass declines in samples proportionally to their distance from continents. Biomass is proportional to food input. (Reproduced with permission from Gage JD and Tyler PA (1991) *Deep-Sea Biology*. Cambridge: Cambridge University Press.)

zone is the realm of the diurnally (daily) migrating organisms and extends from 200 to 2000 m depth. This is the deepest into the water column that light penetrates. Diurnal migration is triggered by light and typically involves moving into shallow waters at night and deeper water layers during the day. Possible reasons for such vertical migration may include hiding in the dark depths from predators during daylight and energy conservation achieved by spending part of the time in deeper, colder water layers, thus allowing organisms to reduce their metabolic rate. The bathypelagic (2000 to 6000 m) and abyssopelagic are the aphotic zones, where there is perpetual darkness (Table 1).

The Fundamental Processes Controlling Marine Biodiversity

There are three major differences between marine and terrestrial systems that have an enormous impact on biodiversity. The first is that the oceans are three-dimensional; organisms live, feed, and reproduce at all levels in the water column. The second is that light has low penetration through sea water, so photosynthesis only occurs in the upper water column, the photic zone, so most of the oceanic system has no primary

production. The third is that most photosynthesis is carried out by tiny single-celled organisms. Macrophotosynthetic organisms (macroalgae or seaweeds) are rare and tend to be concentrated in a thin zone around the edge of the continents in the littoral and sublittoral regions.

Pelagic organisms in the three-dimensional water column have no structure to "hide" in, either for ambush attacks or defense. Essentially, there are only three possible life strategies. An organism can evolve for speed and agility to capture prey and escape predators, or an organism can evolve as a jelly, offering a poor food return for potential predators. A third strategy is rapid growth and reproduction resulting in huge numbers: schools and swarms offer protection to those within. Many pelagic organisms show a patchy distribution for this reason. The organisms within the sediment, the infauna, exist in a two-dimensional world that has a physical structure within which organisms may shelter. The marine system, with regard to biodiversity, may therefore be divided into two separate domains, the pelagic and the benthic. Some infaunal taxa have a pelagic phase and so have a presence in both domains. We may predict that marine pelagic diversity should be lower than terrestrial diversity given the limited choice of life strategy of pelagic organisms coupled with the active or passive mobility of organisms through the water column. The

benthic domain is structurally similar to the terrestrial environment and may be predicted to have a similar diversity with the caveat that the absence of large photosynthetic organisms removes an entire biotope.

The lack of primary production in most of the oceanic realm results in a dependence on an organic flux that originates on land or in the photic zone. The organic flux becomes weaker further away from the continents or deeper into the water column. The weakening flux gradient governs benthic biomass, which declines with depth and distance from the continental shorelines. The Russian grab-sampling programs of Belyaev and colleagues from the 1950s onward established the global distribution of benthic biomass (Figure 1). Productivity has a major influence on biodiversity so the organic flux gradient also will have an impact on benthic biodiversity patterns.

Physical disturbance is also considered to be a key process controlling biodiversity. Physical disturbance was considered to be highest in the littoral region and to decline consistently with water depth down to the abyssal plain. Recent research has caused science to modify this view, as there is now good evidence for hydrodynamic disturbance and seasonal perturbations right down onto the abyssal plain. But in general, the trend is for physical disturbance to decrease with depth. The main physical disturbance processes that show a depth trend are mechanical effects (current energy and wave action), temperature variation (including exposure in the littoral region), and salinity change. Deep trenches are possibly highly disturbed due to slumping of the trench sides.

Sampling and Assessing Marine Invertebrate Biodiversity

Benthos

Marine invertebrates are divided into three size classes on the pragmatic basis of the equipment used to collect them (Table 2). Megafauna are large, visible animals that may be seen by eye (or on photographs). Macrofauna are infaunal (sediment dwelling) organisms that are not normally visible but are retained on a 1 mm sieve (0.5 mm or less in the case of deep-sea samples). Meiofauna are the infauna too small to be retained on such a sieve. It is not clear whether these arbitrary classifications also have biological significance. Some taxa are almost entirely in one size class for their entire life history; for example, nematodes are always considered to be meiofauna. Others—for example, polychaetes, although predominantly in one size class, in this case macrofauna—may also have meiofaunal and megafaunal representatives for at least part of their life history. Warwick and colleagues have some evidence, most convincingly from coastal sandy sediments, that the division of organisms into macro and meiofauna is ecologically meaningful. It appears that organisms must be either macrofaunal-sized, to actively burrow through the sediments, or meiofaunal-sized, to slip between the sediment particles, but mechanical limitations prevent them being of intermediate size.

Megafauna are numerically dominated by the phylum Echinodermata, although the Crustacea are also important. The most abundant and diverse macrofauna group are the

Table 2 Examples of marine benthic invertebrate taxa classified into the three size groups

Size class	Megafauna	Macrofauna	Meiofauna
Collecting equipment	Agassiz trawl, epibenthic sled, anchor dredge	Grab, corer (notably the USNEL box corer)	Corer (notably the SMBA multiple corer)
Examples of taxa	Ascidacea (sea squirts) Asteroidea (sea stars) Brachiopoda (lamp shells) Bryozoa (moss animals) Coelenterata (sea firs, jellyfish, sea pens, sea fans, sea anemones, corals) Crinoidea (sea lilies, feather stars) Crustacea (amphipods, barnacles, crabs, prawns shrimps) Echinoidea (sea urchins) Echiura (worms with elongate bifid proboscis) Hemichordata (acorn worms) Holothuriidea (sea cucumbers) Ophiuroidea (brittle stars and basket stars) Pogonophora (including vestimentiferans) Porifera (sponges) Pycnogonids (sea spiders)	Arthropoda (amphipods, crustaceans, cumaceans, isopods, mites, tanaids) Mollusca (aplacophorans, bivalves, chitons, gastropods, scaphoda) Oligochaeta ("earth" worms) Phorinda Pogonophora (tube worms) Polychaeta (segmented sea worms) Priapulida (worms) Nemertea (ribbon worms) Sipuncula (peanut worms) Turbellaria (flat worms)	Nematoda (thread worms) Copepoda (mainly harpacticoids) Gastrotricha Kinorhyncha Loricifera Ostracoda Tardigrada (water bears) Turbellaria (flat worms)

Figure 2 The invertebrate animals found in a 0.25 m^{-2} layer of sea sediment from the central North Pacific by Hessler and Jumars. A worm shape is the most common body form, nematodes being particularly abundant. Note that the size of the animals is exaggerated so that they may be seen. (Reproduced with permission from Gage JD and Tyler PA (1991) *Deep-Sea Biology*. Cambridge: Cambridge University Press.)

polychaete worms (Annelida), while meiofaunal nematodes (Nematoda) dominate the benthos, at least in terms of abundance and diversity of meiofauna. Arthropods are also important in both the macro and meiofaunal size classes. The average marine benthic infaunal invertebrate is a soft-bodied worm (Figure 2), but vermiform animals are less important components of the megafauna.

Littoral benthos from sediments is sampled by inserting a corer into the deposits and washing the removed sediment over an appropriately sized sieve. Sampling offshore is more problematical. Megafauna are collected by equipment such as Agassiz trawls, anchor dredges, or epibenthic sledges towed along the bottom. Such equipment has problems collecting consistent samples and is suitable only for producing qualitative or semiquantitative data. Initially, the smaller infaunal animals were collected with grabs, and these are still used where circumstances dictate but they are inefficient. The development of the box corer by Hessler and Jumars was a critical improvement in the accurate quantitative sampling of macrofauna for biodiversity studies. Development of quantitative meiofauna samplers, notably the Scottish Marine Biological Association's multiple corer, similarly revolutionized investigation into offshore meiofauna biodiversity.

Marine samples taken with modern corers provide data that are more quantitatively accurate than most terrestrial studies, and this has influenced the type of biodiversity questions asked by marine scientists. Marine research has focused on alpha, or ecological, diversity, which is commonly analyzed using diversity indices that incorporate some measure of evenness as well as species richness. The two most common indices employed are the Shannon-Wiener information function (H') and, in the deep sea, the Sanders rarefaction method expressed as a curve or index that predicts an expected number of species per number of individuals in a sample. Terrestrial biodiversity analysis tends to focus on

larger scale measures of diversity based on species richness per area so it can be difficult to compare published marine diversity patterns with those obtained for terrestrial environments.

Pelagos

Functional classification of pelagic organisms is based on locomotion, size, and trophic level or ecosystem function. Plankton are generally passively drifting organisms carried by water movements; examples include bacteria, algae, and small animals. Nekton are actively swimming organisms and so can to a certain extent migrate in the horizontal plane; examples include squid, fish, and some crustaceans. Phytoplankton, marine plants, are primarily unicellular and responsible for primary production. They are the main food source for all life in the open ocean. Zooplankton are animals with a planktonic life style.

Division of pelagic organisms into size classes is related to retention by the different mesh sizes of nets and filters used for sampling (Table 3). Pico and nanoplankton are usually collected with remotely operated opening and closing bottle devices, allowing control of the depth zone sampled. To collect organisms sized from microplankton upward, various types of net sampling gear are used ranging from simple ring nets, which are hauled vertically, to complicated remotely operated opening and closing net systems that can sample horizontal depth layers (e.g., RMT net, Omori net). Nekton are sampled with large, pelagic fish trawls. Often pelagic samplers are used in combination with other equipment that measures physical factors such as depth, temperature, salinity, and light.

Due to the vastness of the pelagic realm relatively little has been studied, although there has been reasonable geographic coverage. It is estimated that less than 5% of its huge volume

Table 3 The size classes of pelagic organisms with typical examples

<i>Planktonic</i>	<i>Picoplankton</i>	$< 2 \mu\text{m}$	<i>Bacteria</i>
	Nanoplankton	2–20 μm	Bacteria, algae, protists
	Microplankton	20–200 μm	Algae, heterotrophs
	Mesoplankton	0.2–2 mm	Copepods
	Macroplankton	$> 2 \text{ mm}$	Shrimps, fish larvae, jellyfish
<i>Nektonic</i>	Micronekton	$> 2 \text{ cm}$	Small fish, squid, crustaceans
	Nekton	$> 5 \text{ cm}$	Fish, squid, marine mammals

has been sampled once! Deep-sea and very small planktonic species are particularly undersampled; undoubtedly many new species wait to be discovered.

One of the main problems with sampling the benthic and pelagic realm is that scientists are literally grabbing in the dark. In contrary to terrestrial research, where the scientist has a visual concept of the environment and can generally “see” what he or she is doing, marine biologists are completely dependent on remotely operated equipment. This has hampered progress in forming concepts of the marine environment as an ecosystem and estimating its biological diversity. Remotely operated vehicles (ROV’s) with cameras and sampling devices have improved our understanding of the marine environment significantly in the past decade. The choice of sampling gear has a large impact on the representativeness of the samples for the community as a whole, hence the frequent discoveries of new species or new information about known species. Giant squids present a nice example of a species that have eluded biologists.

Taxonomy

Estimating, let alone listing, to the number of described species on the earth is a difficult task. For some groups of organisms, usually terrestrial, the actual number of species is reasonably well known with most species named and described; examples include birds, mammals, and higher plants. Other groups have not been comprehensively researched and accurate estimates for species numbers are not available. This category includes beetles, mollusks, and nematode worms. The current best estimate given by the Global Biodiversity Assessment is that there are 1.75 million species known to science. The estimate for the total number of existing species on earth is approximately 12 to 13 million although some scientists think that it may be as high as 20 million.

Classifying and naming the 1.75 million known organisms is an enormous task, but it is vital for comparing and exchanging biodiversity information between different organizations and countries. A profession of approximately 5000 experienced taxonomists worldwide is performing this documentation task. The Kingdom of Plants is the best known and that of Protists least. For the Kingdom Animalia only 20,000 new names are described yearly, including 17,000 species descriptions. The natural history collections stored and maintained in various countries are an important archiving tool for research, and they provide the community at large with a systematic insight into species diversity.

Inventorying marine invertebrates poses exceptional problems. In an area of survey twice as large as the terrestrial environment, marine biology has to deal with problems of the difficult accessibility of the deep sea and the vagueness of the three-dimensional biogeographical borders of the pelagic realm. This makes stock assessments and the definition of distribution ranges extremely problematical.

Species richness is unevenly distributed over the various kingdoms and phyla. The Kingdom Animalia represents the greatest numerical diversity, with well over 1.3 million known species. The terrestrial order of Insecta, in the phylum Arthropoda, takes up about 70% of the known animal diversity.

In both terrestrial and marine domains, the highest diversity is found in the equatorial region. The productivity (in grams carbon per m^2) is more or less equal: 2.2 g C/ m^2yr in tropical rain forests and 2.5 g C/ m^2yr in coral reefs. In the aquatic environment, current data suggest that coral reefs are the most species-diverse regions and that they are comparable with tropical rain forests. Although reefs only form 0.2% of the seafloor by area, they harbor over 25% of all known marine species. The deep-sea is also believed to be highly diverse. Due to the difficulties in accessing this environment relatively little is known and the discovery of many new species is expected in the coming years (Table 4).

It is often surprising for nontaxonomists to discover that most species in the world have never been described and most probably will never be described. This is especially true for the smaller size classes and marine infauna in general. Marine species have received less attention from systematists than terrestrial organisms, less than 15% of described species are marine. It is estimated that there are at least 200,000 known animal species and about 50,000 known plant (algae) species in the oceans. Fish (26,000 species) and marine mammals (250 species) belong to the best known taxa.

Most marine animals live in the deep sea or are tiny and were out of sight and out of mind. Only in the second half of the 20th century has the equipment become available to comprehensively collect deep-sea and small planktonic organisms, and it is still an expensive business limited to a handful of professionals. When this is compared with the long and vigorous tradition of both professional and amateur taxonomic study in the terrestrial domain, the backwardness of marine invertebrate systematics is understandable.

The taxonomically best known marine area in the world is the coastal strip along northwest Europe and to a lesser extent the coasts of the rest of Europe and North America. Outside these zones, less than half the marine invertebrate species are

Table 4 Known and estimated species diversity of various taxa, including Global Biodiversity Assessment (GBA)

Brachiopoda	1	2
Ectoprocta	1	1

known to science. For example, a recent study of 16 box cores taken from bathyal depths off the British coastline revealed 304 polychaete species, of which only 17% could be associated with a known species. A study of 6 liters of coral reef sediment from Hawaii found 158 polychaete species, of which only 30% had been previously described. The largest study of macrofauna ever undertaken in the deep sea in the bathyal, northwest Atlantic counted 798 infaunal species from 233 box cores, but less than half could be named (Table 5). This study illustrates the importance of polychaetes. In general, at least half the macrofauna species of any deep-sea sample will be new to science.

The systematics of meiofauna is even less well known. For example, a nematode study in the Arctic Ocean reported that only 4% of the 92 species found were known to science, while a study in the Venezuela Basin could only name 1.5% of the 136 species found. The taxonomic breakdown of different meiofauna groups in a single region has not been properly explored due to the difficulty of gathering the disparate taxonomic expertise. Some taxa, such as turbellarians, may be

Table 6 Species diversity per m² of a mudflat from a British estuary for some of the major meiofauna groups

<i>Taxa</i>	<i>Number of species</i>

important but are commonly ignored in samples because they are so difficult to identify (Table 6).

The identification of marine benthic invertebrates is problematical not just because of lack of taxonomic coverage but because the taxonomic state of the art is inadequate. For many of the soft bodied groups, the species concept (i.e., the criteria used to define a species) is poorly defined. For example, the apparently well-known opportunistic polychaete species *Capitella capitata* and *Streblospio benedicti* have been found to be a complex of genetic sibling species (15 in the case of *C. capitata*).

The lack of species descriptions of small marine animals makes it difficult to assess regional diversity, and this is another factor that encourages marine biologists to consider diversity only over small scales. Only marine megafauna have an adequately censused taxonomy.

Global Diversity

It is impossible accurately to assess the total number of species in the oceans because of limited sampling, the nonrandomness of sampling locations, and inadequate taxonomy. The best estimate has come from Grassle and Maciolek, who sampled benthic macrofauna for 176 km along a bathymetric

gradient 1.2 km to 2.0 km deep in the bathyal zone of the northeast Atlantic. They discovered a rate of species turnover of one new species detected every km. Assuming one new species per km², given that there is 10⁸ km² of deep sea, this implies that there may be up to 10⁸ (100,000,000) species in the seas. Such extrapolation techniques are notoriously inaccurate so this figure should be treated with caution but Grassle and Maciolek's calculation is surprisingly similar to the estimate obtained for insect diversity of rain forests by Erwin who used substantially the same technique, suggesting that marine benthic and terrestrial diversity may be similar. A much better knowledge of the geographic ranges of the smaller benthic organisms is essential for an accurate estimation of global marine diversity. This will only be possible when some of the taxonomic problems surrounding these organisms are resolved.

The marine environment certainly demonstrates a greater diversity at higher taxonomic levels than the terrestrial domain. Life evolved in the oceans and many phyla never evolved to survive in the harsher terrestrial environment. It is highly likely that new metazoan phyla remain to be discovered, especially among the small organisms in marine sediments. The free-living phylum Loricifera was only described in 1983 and the commensal phylum, Cyclophora, was first found in 1995 (Table 7).

The distribution of benthic invertebrate species richness around the global ocean basins has not been comprehensively assessed. Schopf has shown that both ectoprocts and bivalve mollusks are twice as diverse in the Pacific than the Atlantic. This may reflect the relative sizes of the two oceans, or it may be the product of the relative age of the basins; the Atlantic is younger than the Pacific.

There is still some controversy over whether the highest marine benthic invertebrate diversity is found in coastal regions or the deep sea. Certainly the deep sea is a much larger environment than shallow water, so it might be expected to be home to more species; but it is unclear whether it is more diverse per area sampled. Originally, the low abundance of animals found in the deep sea caused scientists to assume that the highest diversities must occur on the coastal shelf.

Table 7 Comparison of free-living invertebrate diversity of terrestrial and marine environments at a high taxonomic level

Endemic marine phyla	Endemic terrestrial phyla	Cosmopolitan phyla
Brachiopoda	Onychophora	Annelida
Chaetognatha		Arthropoda
Ctenophora		Chordata
Echinodermata		Cnidaria
Echiura		Ectoprocta
Gnathostomulida		Gastrotricha
Hemichordata		Kamptozoa
Kinorhyncha		Mollusca
Loricifera		Nematoda
Phoronida		Nemertea
Placozoa		Platyhelminthes
Priapula		Porifera
		Rotifera
		Sipuncula
		Tardigrada

However, in the 1960s Saunders found the deep sea unexpectedly diverse, indeed with a higher species richness than shallow water. A series of studies appeared to confirm this view but recently an analysis has reopened the debate. Gray carried out a similar study to that of Grassle and Maciolek (noted earlier) but on the Norwegian coastal shelf. He found a similar, or even higher, rate of accumulation of species with sampling on the shelf compared to the deep sea.

Pelagic Diversity Patterns

Van der Spoel and Heijman summarized the general distribution pattern types and biogeographic regions in the open ocean for phyto- and zooplankton species as Arctic, Subarctic, Cool-Temperate, Warm-Temperate, Tropical, Temperate and Subtropical, Subantarctic, and Antarctic. These regions principally reflect seawater temperature and latitude. Contrary to earlier beliefs, relatively few plankton and nekton species have a true cosmopolitan circumglobal distribution. Despite the lack of obvious barriers in the oceans, there is a surprising variety of the types of species distribution. Species specific characteristics and ecosystem relations play an important role in combination with abiotic factors in determining distribution patterns, but many are further modified by regional influences such as ocean basins, currents, and divergence and convergence zones. Typical and easily recognizable biogeographic patterns are belt-shaped patterns related to latitudes (temperature regimes) and neritic distributions (basically around the continental coasts and shallow water areas). The distribution around the Antarctic continent of *Euphausia superba* (the shrimp commonly known as krill) is an example of a neritic distribution (Table 8).

Many widely distributed pelagic plankton species show North-South or East-West variation. Without active migration, genetic contacts between populations from one end of the range to the other are limited or even nonexistent, promoting genetic drift. In addition, the differing environmental circumstances (abiotic and biotic) at the ends of each range can give rise to phenotypic differences. This is reflected by both morphological and ecological variation within a species, a first step toward the development of new species. An example of North-South variation is found in the shell shape and size of many species of Pteropoda (pelagic Mollusca). East-West variation can be found for example in *Eucalanus subtenuis* (copepod, Crustacea).

It is expected that over coming decades, knowledge of pelagic biogeography and open ocean distributions will develop exponentially (Table 9).

Benthic Large-Scale Diversity Patterns

Latitudinal Gradients

Latitudinal gradients of terrestrial taxa commonly display a decline in species richness from the equator to the poles. Many different processes have been suggested to explain such gradients including competition, predation, mutualism, parasitism, and host diversity, but the most convincing explanation is that the diversity gradient follows the gradient of

Table 8 Pelagic distribution patterns

Type	Region	Example species
Circum-global	Cosmopolitan	<i>Stylocheiron maximum</i>

Total	48	53	41	171	139	123	55	60	45

solar energy. There are two potential mechanisms that might cause this relationship. One suggestion is that latitudinal gradients in solar radiation cause concomitant gradients in productivity and hence diversity. The other suggestion is that the relationship between solar energy and diversity is the result of increased evolutionary speed in warmer conditions. The explanations are not mutually exclusive.

The relationship between latitude and diversity for marine benthic coastal fauna could best be described as confusing, with different studies and different taxa yielding conflicting results. For example, if the diversity of core samples is compared using diversity indices, then no significant difference is found between tropical and temperate samples. This experiment has been repeated for both macrofauna by Warwick and colleagues and meiofauna by Boucher and Lambshead.

However, Roy and colleagues were able to test for a latitudinal diversity gradient for prosobranch, gastropod mollusks using data based on number of species per degree of latitude. Unusually for marine studies, this data is similar in scale and format to the terrestrial diversity data used for analyzing large-scale patterns and it is noteworthy that it produces convincing latitudinal diversity gradients (Figure 3). Furthermore, the prosobranch diversity gradient follows the solar energy gradient in a similar way to terrestrial latitudinal gradients.

The deep sea is an intriguing location to search for latitudinal gradients because solar energy can have no direct

Figure 3 The number of American coastal species of prosobranch gastropods per degree of latitude. On both coastlines the diversity peaks at 10 to 30° N. (Reproduced with permission from Roy K, Jablonski D, Valentine JW, and Rosenberg G (1998) Marine latitudinal diversity gradients; tests of causal hypotheses. *Proc. Natl. Acad. Sci. USA* 3699–3702.)

impact on deep-sea diversity. The deep sea is uniformly cold and relatively stable so it can be argued that temperature cannot be a factor in controlling diversity though influencing evolutionary rates. Furthermore, productivity gradients in the deep sea are the result of gradients in the food flux to the seafloor, which vary according to a number of processes.

Figure 4 The change in species diversity with latitude for Atlantic deep-sea (a) isopods, (b) gastropods; and (c) bivalves. Rex and colleagues demonstrated that species richness for these taxa falls from the equator northward into the Norwegian Sea. Species richness has been calculated using the Sanders rarefaction index. (Reproduced from Rex, *et al.* 1993, with permission from Nature.)

Rex and colleagues found that deep-sea gastropod mollusks, bivalve mollusks, and isopods showed a decline in diversity from the equator to the Norwegian Sea in the North Atlantic (Figure 4). The explanation is not obvious, as productivity tends to increase northward. Similar gradients have been searched for in the South Atlantic by Brey and colleagues but have not been found, so it is possible that the North Atlantic gradient is due to some individual feature of this ocean, possibly the Quaternary glaciation.

Analysis of the smaller invertebrates by Lamshead and colleagues has shown different patterns. Nematode diversity appears to be correlated with the food flux to the seafloor (i.e., a productivity gradient). In the North Atlantic, there is a weak increase in diversity northward. In the Pacific, nematode diversity declines northward away from the equator, as does the food flux to the seafloor (Figure 5).

Figure 5 The count of the number of nematode worm species per station in the North Atlantic plotted against latitude. There is a gradual increase in species richness following the increase in food supply from the equator northward. This pattern extends as far north as the Norwegian Sea (marked NS) where there is a marked drop in species richness. The pattern of diversity being positively linked to food input appears widespread for small invertebrates.

Bathymetric Gradients

Bathymetric gradients are probably better understood than any other large-scale diversity pattern for marine benthic invertebrates and for once a consistent pattern is found in all size classes. Rex showed that a number of macrofaunal taxa followed a parabolic diversity curve with depth, diversity peaking at about 2 to 3000 m (Figure 6). A number of studies have since confirmed this finding. A similar pattern was found for megabenthos by Haedrich and colleagues and for nematodes by Boucher and Lamshead (Figure 7).

The exact peak in each bathymetric diversity gradient varies with different taxa and with different locations and, for all we know, there may be temporal variations. However, the basic pattern of diversity peaking in the bathyal or upper abyssal region appears consistent. This consistency suggests that similar processes are responsible for all taxa and locations. Two obvious explanations are that both productivity and disturbance decline with depth. Computer models (e.g. those produced by Huston) have demonstrated how the interaction of productivity and disturbance gradients can theoretically give parabolic diversity patterns.

The exact species composition of the benthic community changes rapidly with depth for some taxa with species having a preferred depth range. Other taxa have wide depth ranges. This has been better studied for the larger organisms than for small organisms due to taxonomic reasons. A wide variety of reasons probably explain the different strategies displayed by different taxa but, in general, the sharpest discontinuity is found at the shelf break with a second boundary at about 1000 and 2000 m. So the basic pattern is of zones of gradual change in species composition separated by areas of rapid change.

Benthic Small-Scale Diversity Patterns

One of the most intriguing observations about marine benthic invertebrates is the high species richness found in individual core samples (Table 10).

Figure 6 The relationship between gastropod diversity, as measured by the Sanders rarefaction index, and depth in 85 epibenthic sledge samples from various locations in the Atlantic Ocean and Norwegian Sea. Rex and colleagues showed that diversity peaks at bathal depths declining in both shallow and deeper sediments. The pattern is probably caused by the effects of disturbance and food availability on diversity. Note that the regression lines and 95% confidence limits are for the samples from the North American Basin only. (Reproduced with permission from Ormond RFG, Gage JD, and Angel MV (eds.) (1997) *Marine Biodiversity, Patterns and Processes*. Cambridge: Cambridge University Press.)

Figure 7 The species richness of marine nematodes in sediments from six biotopes, temperate estuaries, tropical shallow water, temperate shallow water, bathyal depths, abyssal depths, and hadal depths. Species richness is measured using the Sanders rarefaction index. Diversity is highest in bathyal sediments.

The observation that a large number of similar species can be found together in samples of apparently featureless sediment has always represented a challenge for “equilibrium” explanations for the ecological processes that control diversity. Such explanations depend on the hypothesis that coexisting species must avoid competition by each possessing some unique adaptational specialization. This hypothesis is difficult to accept for such a simple organism as a free-living nematode worm, many of which seem to have similar functional requirements.

An alternative explanation is that large numbers of species can coexist because the sediment is divided into transient

Table 10 The species diversity of nematode samples from different depths and habitats from the British Isles westward into the deep sea

Location of sample	Depth m	Species richness	Number of individuals studied
Clyde Estuary	High water, beach	20	272

Rockall Trough	1474	56	127
Porcupine Abyssal Plain	4840	71	493

patches by biological and physical small-scale disturbance and uneven distribution of the vertical food flux. Grassle and colleagues have coined the phrase *spatio-temporal mosaic* to describe this process (Figure 8). A new patch is initiated by a disturbance event, or a food fall, and colonization to exploit the new situation increases diversity. As the patch ages and is exploited, competition increases and diversity drops. But at some point, a new event will recreate a new patch. In this theory, the sediment consists of a heterogeneous mosaic of unique patches of different ages and histories. For any given species, there is a suitable habitat within dispersion distance in

Figure 8 The spatio-temporal mosaic theory of Grassle and colleagues. The concept is that the sediments consist of a series of patches, each of which evolves through an unpredictable cycle. The example shows three patches, A, B, and C through times T_1 , T_2 , T_3 , and T_4 . Each vertical bar is a species and the height of the bar represents the abundance of that species. At T_1 , patch A is physically disturbed removing all the animals by T_2 . The patch is recolonized from the water column (dark arrow) and by migration from adjacent patches (light arrow). By T_3 and T_4 , the patch is diverse with six species, five of which are equally abundant. Patch B is undisturbed through time. As the patch matures and is exhausted, the diversity drops to four species through competition. One of these species becomes completely dominant. Initially, patch C is similar to patch A, but it is biologically disturbed by the feeding behavior of a large organism at T_2 . This empties the patch allowing recolonization, forming a diverse community. This theory explains how apparently featureless marine sediments can support such a high diversity of life. For any species there is always a suitable new patch available nearby when it exhausts or is outcompeted in its current location. From Paterson.

the mosaic, and when that patch becomes unsuitable, another opens up nearby. The theory depends on limited large-scale disturbance and a lack of barriers for dispersion so it is considered most applicable to the deep sea (and possibly rain forests!).

This spatio-temporal mosaic theory predicts that areas of the deep-sea subject to a flux of phytodetritus would have a more patchy distribution of animals and higher species diversity than other locations. This has been tested for nematode worms by comparing the small-scale spatial distribution and species diversity of nematodes from a station in the phytodetritus-enriched Porcupine Abyssal Plain with a station from the more oligotrophic Madeira Abyssal Plain. Nematodes from the enriched site were more diverse and more species showed aggregation. Interestingly, the species were not aggregated in concordance together around the food or evenly randomly aggregated with respect to each other but showed discordance (i.e., species tended to aggregate in different places). This is consistent with Grassle's theory.

Diversity Over Evolutionary Time

The marine fossil record is more complete than the terrestrial because the ocean floor tends to accumulate sediment. Even so, only certain fauna, notably those with "hard parts," will form an adequate fossil record. The dominant macrofauna group, the polychaetes, presents a limited fossil record, and the dominant meiofauna group, the nematodes, has no record at all. The available fossil record suggests that marine species have an existence of about 4 million years. This indicates on average a 25% species turnover per million years. Assuming that the oceans contain 10^7 (10,000,000) species, we might predict that 2.5 species would become extinct due to natural processes every year. In practice, the fossil record suggests that there are periods of relative quiescence followed by mass extinction and subsequent speciation. The fossil record also implies that 95% of all the marine species that have ever existed are extinct.

The history of marine biodiversity is best tracked at the family rather than the species level to remove some of the

noise associated with an incomplete fossil record. This does tend to make the mass extinction events appear less dramatic. For example, only 54% of marine families were lost in the Permian extinction event, but it is estimated that 77 to 96% of all species became extinct.

The early Cambrian shows a rapid increase in diversity that tends to flatten out in the middle and late Cambrian (Figure 9). Most animal phyla appear in the record in this phase. The Cambrian diversity includes a number of "archaic" forms such as trilobites, hyoliths, and inarticulate brachiopods that decline after the Cambrian period. Diversity is not high in the Cambrian and rather unspecialized detritus and low suspension feeding organisms functionally dominate communities, suggesting a simple ecology.

The Ordovician sees a steep rise in diversity but the curve then flattens for some 200 million years. Periods of mass extinction are detectable, notably at the end of the Ordovician and in the late Devonian, but in general diversity stabilized. This new Palaeozoic diversity was associated with an evolutionary radiation of sessile benthic organisms such as crinoids, articulate brachiopods, stenolomate bryozoans, and tabulate and rugose corals.

The Palaeozoic period ended with the catastrophic Permian-Triassic mass extinction. Diversity then apparently rose steadily, with a small extinction at the end of the Cretaceous, past the levels achieved in the Paleozoic until the unique peak of the present day. Current family diversity is apparently twice as high as the Palaeozoic stable level. The Palaeozoic community never seems to have recovered and the modern high diversity is associated with a new fauna of shell-breaking predators and sediment movers. This fauna includes the familiar sea urchins, bivalve and gastropod mollusks, and crustaceans such as shrimps and crabs.

A variety of explanations have been given for this pattern. A number of authors have pointed to the association between the rise in taxonomic diversity and a rise in functional diversity. This almost certainly explains the Ordovician increase in diversity, which is essentially because of increased exploitation of marine sediments. Explanations for the Mesozoic-Cenozoic explosion in diversity are more controversial. One argument is that the breakup of the Pangaea supercontinent caused increased diversity through increased climatic variation leading to more endemism. It is not clear how this argument would

Figure 9 The family diversity of marine animals as measured by their fossil record from 600 M years ago to the present day. Graph C shows the rise and fall of the diversity of the Cambrian fauna of unspecialized detritus and low suspension feeding organisms, P shows the rise and fall of the diversity of the Palaeozoic fauna of sessile benthic organisms, and M shows the rise of the diversity of the modern fauna of sediment movers and shell breaking predators. Note that sampling error may have exaggerated modern diversity. The arrows indicate periods of mass extinction, 1 is at the end of the Ordovician, 2 in the late Devonian, 3 at the end of the Triassic, and 4 at the end of the Cretaceous (the dinosaur extinction). P indicates the massive Permian extinction. (Graph by Sepkoski, 1992, reproduced with permission from Heywood VH (ed.) (1995) *Global Biodiversity Assessment*. UNEP, Cambridge: Cambridge University Press.)

apply to the deep sea, where the bulk of marine diversity is to be found. Another suggestion is that evolution in the exploitation of the terrestrial domain has increased nutrient runoff into the oceans concomitantly increasing marine diversity. A similar argument has combined these two explanations suggesting that volcanism associated with continental breakup increased nutrient flux into the oceans.

Finally, Raup has suggested that the high modern marine diversity is an artifact of the fossil record. He observed that across the Mesozoic-Cenozoic time periods there are more younger rock available for study than older rock. If **Figure 9** is adjusted to allow for this, then there is a slower recovery from the Permian mass extinction and modern diversity peaks at much the same level as in the Palaeozoic. If true, it implies that there is a maximum global carrying capacity for marine biodiversity and that the Permian-Triassic extinction was even more devastating than **Figure 9** suggests since the new graph would show that the Palaeozoic benthic fauna has declined consistently since the extinction event. This is possible as the new Mesozoic fauna included many organisms that would tend to disrupt the stable sediment environment on which the sessile Palaeozoic fauna depended.

Hydrothermal Vents and Cold Seeps

The special biological communities around hydrothermal vents were first discovered in 1977 on the Galapagos Rift at a depth of 2500 m. They are now known to be widely distributed in the oceans at tectonically active sites such as subduction and fracture zones, ocean-floor spreading centers, and back-arc basins. Vents are formed where sea water penetrates through fissures in the ocean floor deep into the earth's crust. The water becomes heated and escapes back to the surface through hydrothermal vents. The water temperature at a vent varies from mildly warm, 23 °C, to superheated, 350 °C and can be rich in sulphide and metalliferous ions. The hottest vents are called "smokers" from the precipitation of minerals in the water.

Cold seeps that release sulphide and methane-enriched water have been recorded from a number of areas in the Atlantic and Pacific Oceans. Similar chemical conditions have been found around whale carcasses that are oil rich.

These sulphide-rich habitats are small and ephemeral. The evidence is that many have a life span that measures in decades, although cold seeps may last longer. However, they do appear to be commonplace and may be thought of as chains of islands across the seafloor, separated by distances of 1 to 100 km.

Vent communities have a noticeably different biodiversity from the surrounding ocean floor. The fascinating feature of vent communities is that they derive their energy from chemosynthetic primary production, by reducing compounds such as hydrogen sulphide, rather than photosynthetic sources. It is not clear whether these communities are entirely chemically independent of the photosynthetic world but certainly they are energetically independent.

Biomass is high at hydrothermal vents and primary productivity may be double or triple that of the overlying water. Dense mats of bacteria are found, notably *Thiomicrospira*.

A number of invertebrate species feed in dense colonies either directly on these bacteria or by means of symbiotic chemoautotrophic bacteria. Evolutionary selection pressure has been for large, fast-growing species at these productive but ephemeral sites.

Conversely, species diversity is much lower at vents than at other benthic habitats, illustrating once again Rosenzweig's "paradox of enrichment." The dominant species vary from place to place and from depth to depth. For example, the shallow vents off the Palos Verdes Peninsula in California are dominated by the black abalone, *Haliotis cracherodii*; the Mid-Atlantic Ridge vents are characterized by two species of caridean shrimp; and the Eastern Pacific Rise and Galapagos Spreading Centre vents are dominated by the red-plumed, tube dwelling vestimentiferan worms (notably *Riftia pachyptila*) and the large bivalves *Calyptogena magnifica* and *Bathymodiolus thermophilus*. The fauna around the vents are often found to be new to science. Other fauna include a number of polychaetes, crustacea (notably including a number of decapods, and a new primitive genus of barnacle, which is a relic of the Mesozoic).

More than 150 new species, 50 new genera, and 20 new families or subfamilies have been identified with sulphide-rich vents and seeps. Endemism is considered to be high and it is noteworthy that many of the fauna do not appear to be particularly well adapted for high dispersal. Genetic studies on *Bathymodiolus* have shown strong genetic similarity between organisms at sites only 8 km apart but high dissimilarity at sites separated by 2200 km. Vents that are distinctly separated from the chain of sulphide-rich habitats such as the Mariana Trough or Hawaiiin volcanic seamounts do show considerable faunistic differences from the norm and the Atlantic sites are less diverse than the Pacific.

Glossary

Annelida Segmented worms, a relatively species-poor phylum.

Arthropoda Joint-legged animals, the most species-rich phylum existing today.

Enchytraeids Segmented worms that are related to but smaller than earthworms.

Invertebrates Animals without a backbone (vertebrae), ranging from unicellular Protozoa to multicellular, complex organisms such as insects.

Phylum Highest level of taxonomic division in the animal kingdom, followed in descending order by class, order, family, genus, and species.

The Terrestrial Invertebrates

Taxonomic Groups, Fully Adapted to Terrestrial Conditions

The truly successful and well-adapted terrestrial invertebrates belong to only two phyla, Arthropoda (joint-legged animals) and Mollusca (snails, etc.). Other taxa, such as Protozoa, Aschelminthes (nematodes, etc.), and Annelida (earthworms, etc.), are limited by their need of an aquatic or at least water-saturated environment, such as in the litter layer and in soil, and a lack of protection against ultraviolet rays. These groups can only move in the true terrestrial environment during nights with favorable weather conditions.

The Insecta are the largest class of animals. About one million species are described, but there are possibly as many as five million species present in the world today. The bulk of the insect species are in the orders Coleoptera (beetles), Lepidoptera (butterflies and moths), Hymenoptera (wasps, ants, bees), and Diptera (flies) (Table 1 and Figures 1–3). Other Arthropoda that successfully cope with the terrestrial environment include the classes Diplopoda (millipedes) and Chilopoda (centipedes) and the similarly built but smaller and less known Symphyla and Paupoda.

In the class Arachnoidea, scorpions (order Scorpionidea) and spiders (order Araneae) may be the most obvious. However, the smaller mites and ticks (order Acari) are a highly diverse group, containing parasites, predators, fungivores, and detritivores, and are common in almost all litter layers and soils (Figure 4).

The crustaceans (phylum Arthropoda, class Crustacea) are mainly aquatic, but the terrestrial isopods (order Isopoda, the “pill-bugs”) are quite widespread, even in dry climate zones. However, they lack the water regulation of, for example, insects and spiders and are restricted to moist micro-environments and nocturnal habits.

Among the molluscs (phylum Mollusca) only a few classes have terrestrial capability, and the snails (class Gastropoda) have successfully coped with the dry atmosphere by developing a shell into which they can escape.

Taxonomic Groups with Limited Adaptations

The subkingdom Protozoa contains microscopic animals such as flagellates, ciliates, and amoebae. These are found almost everywhere but are restricted to water films or water bodies.

Table 1 Insect orders, common names of typical members, and approximate numbers of described species

Order	Typical members	Number of species
Protura	Telsontails	100
Thysanura	Bristletails, silverfish	700
Collembola	Springtails	2000
Ephemeroptera	Mayflies	1500
Odonata	Dragonflies, damselflies	5000
Orthoptera	Grasshoppers, crickets, cockroaches, mantids	23,000
Isoptera	Termites	2000
Plecoptera	Stoneflies	1500
Dermaptera	Earwigs	1100
Embiopoda	Webspinners	150
Psocoptera	Psocids	1100
Zoraptera	Zorapterans	20
Mallophaga	Chewing lice	3000
Anoplura	Sucking lice	250
Thysanoptera	Thrips	3200
Hemiptera	Bugs	23,000
Homoptera	Cicadas, aphids, hoppers	32,000
Neuroptera	Dobsonflies, fishflies, snakeflies, antlions	4700
Coleoptera	Beetles	277,000
Strepsiptera	Twisted-wing parasites	300
Mecoptera	Scorpionflies	350
Trichoptera	Caddisflies	4500
Lepidoptera	Butterflies and moths	112,000
Diptera	True flies	85,000
Siphonaptera	Fleas	1100
Hymenoptera	Sawflies, wasps, ants, bees	103,000

However, several groups have resting stages that can withstand severe desiccation and have the capacity to rapidly reproduce when conditions improve. Thus Protozoa can regulate bacterial biomass and numbers in the soil.

The phylum Platyhelminthes contains primitive flatworms that lack an anus and sometimes even guts. They are mainly parasitic (e.g., tapeworms), but there are free-living species in the class Turbellaria.

Figure 3 An early micrograph (woodcarving) of a flea (class Insecta, order Siphonaptera). The lettering is not explained in the original. (Reproduced from *Swenska Mercurius*, 1682, with permission from Dal B (1996) *Sveriges Zoologiska Litteratur*. 1483–1920. Kjuge, Sweden: Orbis Pictus.)

Nematodes (phylum Aschelminthes, class Nematoda) are unsegmented, mainly microscopic worms that often have the capacity to form resting stages that can withstand drought and low temperatures. Thus the nematodes have successfully invaded most environments, including arable land (several are pests, but the majority are not) and the inside of other animals (several are internal parasites of mammals, insects, etc.) (Figure 5).

Segmented worms are in the phylum Annelida, class Oligochaeta, and contain the well-known “ecological engineers”—the earthworms. Well over 1200 species of earthworms have been described. Lesser known but very abundant in boreal forests and wetlands are the smaller enchytraeids, which are also segmented (Figure 6).

The Terrestrial Environment

The terrestrial environment is harsher than marine or freshwater environments. Shortage of water, ultraviolet radiation, rapidly fluctuating temperatures, and a number of obstacles against movement and/or the dissemination of offspring create survival problems, but also opportunities for evolution and speciation. The fact that most of the known animal species are terrestrial is due to the diversity of habitats and a fairly high probability for isolation of populations—a necessary condition for speciation.

Invertebrate biodiversity ranges from the very low in the polar deserts (a few insect and nematode species) to the extremely high diversity found in some rain forest areas, particularly of insects. Note that the high biodiversity in rain forest may be due partly to the high humidity, which reduces the environmental limitations of animal groups that have limited terrestrial adaptations (e.g., slugs). The various ecosystems and habitats that harbor terrestrial invertebrate diversity are described elsewhere in the Encyclopedia.

Glossary

Alate An imago still possessing its wings.

Caste A group of individuals in a colony that are both morphologically distinct and specialized in behavior.

Imago The adult insects; the final developmental stage when insects possess wings.

Larva An immature individual without an external sign of wing buds or soldier morphology.

Neotenic A secondary reproductive with juvenile morphological characters. Neotenics derive from larvae, nymphs, pseudergates, or workers through at least one special moult.

Nymph An immature individual on the developmental pathway to the imago and which possesses external wing buds.

Presoldier A transitional morph that always precedes the soldiers; an unsclerotized individual whose head shows signs of soldier differentiation.

Primary reproductives Dealate reproductives that founded a new colony after nuptial flight.

Pseudergate (false worker) A temporarily nonreproductive individual serving the colony in nutrition,

construction, or brood care, which results from a late, reversible deviation from the pathways to the imago and is characterized by reduced wing buds compared to nymphs of the same stage.

Queens and kings Females and males that actively reproduce in a colony.

Secondary reproductives Reproductives that differentiated in an established colony, whatever their origin and morphology. They may be supplementary reproductives if older reproductives are still present or replacement reproductives if not.

Soldier An individual with a strongly sclerotized head showing defensive adaptations, such as enlarged mandibles, a stopperlike shape, or a frontal gland able to produce a defensive secretion.

Worker An individual resulting from an early, irreversible deviation from the pathway to the imago, and performing helper tasks. Workers are primarily characterized by the loss of the ability to proceed to the winged imago, but they need not be permanently sterile.

Introduction

The Isoptera is a relatively small order of insects that consist of 31 orders, including about 2650 described species. The order name Isoptera originates from the fact that the imago (adult) has wings of equal size (*Isos* in Greek meaning the same and *ptera* meaning wings). The insects of Isoptera are commonly called termites in English. Due to their poor abdominal sclerotization and white appearance, they are often called “white ants” in many temperate regions. However, they are not phylogenetically closely related to ants, but to cockroaches and mantises. Termites are sometimes black, reddish brown, or yellow in body coloration in tropical regions.

Termites are widely distributed in tropical and sub-tropical regions, spreading from humid forests to savannas and even arid areas. Their biomass approaches 10 g wet weight/m². Only a few animal groups such as human beings, earthworms, herbivorous mammals in African savanna, and ants claim this order of biomass. The basis of this extraordinary prosperity of termites lies in their feeding habits. They consume cellulose, which is the most abundant organic matter on the earth. The ecological basis of their prosperity is their symbiosis with microorganisms and their highly developed social organization.

The symbiosis produces novel abilities that cannot be attained by either of the partners alone. In particular, the symbiosis between higher organisms and microorganisms often creates capabilities for exploiting new food resources such as dead plant material containing large amounts of cellulose, which is a potential energy source but difficult for most animals including human beings to utilize. On the other hand, sociality enhances the efficiency of resource exploitation. Either of these or both together may cause a rapid growth and spatial expansion of the population, leading to diversification.

Animals in the tropical rain forests where the species diversity is the highest in the world are characterized by the dominance of social insects (termites, ants, social wasps, and social bees), and the dominance of symbiotic associations. Termites possess both of those attributes. Termites and ants occupy about one-third of total animal biomass in Amazonian tropical rain forests. The symbiosis and sociality in termites, together with their super abundance, brings them to play a keystone role of “super decomposer” of dead plant material in tropical terrestrial ecosystems. They consume and transform a large amount of nitrogen-poor dead plant material into nitrogen-rich termite body, which is in turn consumed by a great variety of animals ranging from ants and spiders to chimpanzees and human beings. Thus they form the basis for a

large food web in the ecosystems, although they are well-known pests of agriculture and wooden buildings.

Furthermore, termites are prominent ecological engineers, modifying the soil properties by constructing huge mounds and long subterranean galleries and providing many animals and plants with heterogeneous habitats. It is also possible that they are an important player in global change scenarios because they have high biomass and emit a large amount of greenhouse gases such as methane as well as CO₂.

There are several landmarks in the process of global diversification of termites: (a) acquisition and loss of symbiotic flagellates, (b) social evolution, (c) change of life type from one-piece type to separate type, and (d) change of dominant feeding habits from wood feeding to soil feeding. This chapter explains an outline of the diversification of termites in relation to those events as well as their ecosystem functions.

A textbook of termites, *Biology of Termites*, was edited by Krishna and Weesner (1969, 1970), and monographs of termites were published by Grasse (1982, 1984, 1986). A new textbook, *Termites: Their Symbiosis, Sociality and Global Diversification*, was recently edited by Abe *et al.* (2000).

Profile of Termites

Phylogeny and Fossil Records

The Isoptera, which includes 280 genera and more than 2650 described species, is a small order, considering that more than 0.9 millions species of insects have been described. Termites include seven families: Mastotermitidae, Hodotermitidae, Termopsidae, Kalotermitidae, Rhinotermitidae, Serritermitidae, and Termitidae. Principal genera of the world termite fauna and their distribution are given in [Table 1](#).

The phylogeny of termites is shown in [Figure 1](#). Three families, Mastotermitidae, Hodotermitidae, and Termopsidae, are the oldest living lineages. These three families together with Kalotermitidae, Rhinotermitidae, and Serritermitidae are called lower termites, which are characterized by the presence of symbiotic flagellates (Protozoa) in the gut. A remaining family, the Termitidae, is made up of the so-called higher termites, which are characterized by the absence of symbiotic flagellates, although some higher termites harbor symbiotic amoeba in the gut. The species diversity is the highest in Termitidae (the higher termites, ca. 1900 species), occupying about 70% of all species, while the Kalotermitidae have the highest species diversity (ca. 410 species) among the lower termites.

The fossil record of termites is fragmentary and has not been known from Africa. The number of fossil and living species of each family is shown in [Table 2](#). The oldest fossil is the worker of *Meiatermes bertrani* (Hodotermitidae) found in limestone deposits in Spain, dating to 130 million years ago (Cretaceous). A related species, *M. araripena*, was discovered in limestone deposits in Brazil, dating to 110 million years ago. The next oldest fossil species is *Valditermes brenanae* (Mastotermitidae) from England dating to 120 million years ago and *V. acutipennis* from Mongolia. Other Cretaceous species include *Cretatermes carpenteri* (Termopsidae), *Luteitermes prisca* (Hodotermitidae), and *Mastotermes sarthensis* (Mastotermitidae). Those Mesozoic termite fossils are found in Europe, Asia, and North and South America, indicating a broad Pangean

distribution in both temperate and tropical habitats. A living termite, *Mastotermes darwiniensis*, whose distribution is confined to Australia, may well be called a living fossil.

Many fossil species of the Kalotermitidae and Rhinotermitidae, as well as Mastotermitidae, Hodotermitidae, and Termopsidae, have been found in the Tertiary period, while only a few fossil species of the Termitidae (higher termites), which have the highest living species diversity, have been found in the Tertiary period.

Thus, the adaptive radiation of the higher termites seems to have occurred in the late Tertiary or Quarternary (Pleistocene) after the breakdown of Gondwana, yet they show a worldwide distribution. This is an interesting problem remaining to be explained because the flight distance of termite alates is usually limited to some kilometers.

Based on the Cretaceous fossil record and living species diversity, two lower termite groups can be distinguished, primitive and modern. Primitive lower termites characterized

by Cretaceous species and low-living species diversity include Mastotermitidae, Hodotermitidae, and Termopsidae. The three families are the oldest living lineage as shown in Figure 1. Modern lower termites characterized by moderate Tertiary and living species diversity include Kalotermitidae, Rhinotermitidae, and probably Serritermitidae.

Distribution

Global generic distribution of termites is shown in Figure 2. Termites occur between the latitudes of 30–45N ~ 40–45S and are mainly distributed in tropical regions, especially in western and central Africa, southeast Asia, northeastern Australia, and South America. The species diversity drops from 10 degrees north and south of the equator, but this gradient is not uniform on both sides of the equator (Figure 3).

The three groups of termites—primitive lower, modern lower, and higher termites—show different distributions. Primitive lower termites show a fragmental or disjunctive distribution. The Mastotermitidae have only one species, *Mastotermes darwiniensis*, which is distributed in the savanna of northern Australia, although more than 20 species of Tertiary fossils are known from Europe, Australia, and North and South America. The Hodotermitidae including three genera (*Hodotermes*, *Microhodotermes*, and *Anacanthotermes*) and 15 species of grass feeders are distributed in the savanna and arid grassland of Africa and Asia although the family was widely distributed (Spain, Brazil, Europe, Japan, United States) in the Cretaceous and Tertiary periods. *Hodotermes* and *Microhodotermes* occur in Africa, while *Anacanthotermes* occurs in north African deserts, the Middle East, and southern India.

The Termopsidae containing 20 living species show an amphitropical distribution: Three species of *Porotermes* are distributed in temperate regions of three southern continents (one species in each of Chile, Australia, and South Africa). Several species of *Stolotermes* are found in Australia, New Zealand, Tasmania, and South Africa, whereas the other three genera are distributed in the temperate and subtropical northern hemisphere (*Archotermopsis* in Kashmir, India, *Zootermopsis* in North America, and *Hodotermopsis* in Japan, Vietnam, and China).

Figure 3 Latitudinal gradients of termite generic richness north and south of the equator. Reproduced from Eggleton, 2000.

Figure 2 Global generic distribution of termites. The darker the square the higher the generic richness. Maximum generic richness is the southern Cameroon square. Reproduced from Eggleton, 2000.

The modern lower termites except the Serritermitidae show a worldwide distribution. The Serritermitidae includes only one species, *Serritermes serrifer* in Brazil, and its phylogenetic position is under debate. The Kalotermitidae are distributed worldwide but tend to be distributed in coastal forests or islands. Among them, *Glyptotermes*, *Cryptotermes*, and *Neotermes* are pantropical, while *Kalotermites* shows a bipolar distribution. The Rhinotermitidae are widely distributed across tropical, subtropical, and temperate regions, and from wet to dry areas. For example, *Psammotermes* is one of the few insects persisting in deserts of Africa, the Middle East, and northwest India. *Coptotermes*, some species of which are serious pests of wooden buildings, are pantropical, partly because they are carried by humans. The distribution of *Heterotermes* and that of *Reticulitermes* are complimentary: *Heterotermes* is distributed in all tropical regions except for Africa, while *Reticulitermes* shows a Holarctic distribution. *Prorehinotermes* is mainly distributed on tropical oceanic islands.

The higher termites, including the four subfamilies of the Termitidae—Macrotermitinae, Apicotermitinae, Termitinae, and Nasutitermitinae—are characterized by central (tropical) distribution. The Macrotermitinae (fungus-growing termites) are distributed in the central areas of tropical Africa and

southeast Asia. Three genera, (*Macrotermes*, *Odontotermes*, and *Microtermes*) are common. The Apicotermitinae include the *Apicotermes* and *Anoplotermes* groups. The *Apicotermes* group, most species of which are soil feeders, is distributed in tropical Africa, while the *Anoplotermes* group, which is a soldierless soil feeder, is distributed in tropical Africa, southeast Asia, and South America. The Termitinae are pantropical, including dominant genera of *Cubitermes*, *Termes*, *Amitermes*, and *Microcerotermes*. The Nasutitermitinae are also pantropical, including dominant genera of *Nasutitermes*, *Trinervitermes*, and *Cornitermes*.

It is interesting to note that the higher termites and some lower termites (the Termopsidae, the Kalotermitidae, and *Prorehinotermes* of the Rhinotermitidae) are complementary in geographic distribution: the former show a central distribution (occupying tropical mainland), while the latter show a marginal distribution (localized in temperate regions and tropical coastal areas and islands).

Termites as Eusocial Insects

An excellent introduction to eusocial insects was given by Wilson (1971). Eusociality is generally characterized by two generations of conspecific adults living together (that is,

Figure 4 The interior of a nest of *Amitermes hastatus* of South Africa. The primary queen and male sit side by side in the middle cell. To the lower left is a secondary queen, which is also functional in this case. In the chamber at top center are reproductive nymphs, characterized by their partially developed wings. Workers attend the queens and are especially attracted to the heads, to which they offer regurgitated food at frequent intervals. Other workers care for the numerous eggs. A soldier and presoldier (nymphal soldier stage) are seen in the lower right chamber, while worker larvae in various stages of development are found scattered through most of the chambers. Reproduced from Wilson EO (1971) *The Insect Societies*. Cambridge: Harvard University Press.

forming a group called a colony) and cooperation with each other to the extent that a strong reproductive skew is observed—that is, only one or a few adults in the group lay viable eggs (i.e., division of reproduction). The interior of the nest of a higher termite, *Amitermes hastatus*, is shown in Figure 4. The primary queen (the largest individual) and king sit in the middle cell. Workers attend to the queen, to which they offer regurgitated food. Developmental pathways of the fungus growing termites are schematically shown in Figure 5.

The eusociality of termites has evolved at least four times as sterile castes (once for the soldier caste and three times for the worker caste). Some wasps, some bees, all ants (Hymenoptera), and all termites (Isoptera) are typical eusocial insects, and sterile members have been found also in gall-forming aphids (Hemiptera) (soldiers), gall-forming thrips (Thysanoptera)(soldiers), an ambrosia beetle (Coleoptera) (workers), some mole-rats (workers), and a coral reef shrimp (soldiers), which are included in eusocial animals.

Termites have similar social organization to the Hymenoptera but differ from them in several important aspects (Table 3). Termites are characterized by the diversity of soldiers, while the Hymenoptera are characterized by the diversity of workers. Furthermore, in termites, (a) females and males are both diploid (whereas females are diploid and males are haploid in the Hymenoptera), (b) females (queens) and males (kings) both take care of brood and male remains with female through life (whereas males are produced just before the mating season and die soon after mating in the

Hymenoptera), (c) workers and soldiers are either male or female or both (whereas they are all females in the Hymenoptera), and (d) termites are hemimetabolous (whereas they are holometabolous in the Hymenoptera).

Food and Predators

Animals are divided into two large groups in relation to their feeding habits: cytoplasm consumers and cell wall consumers. Most termites are cell wall consumers, whereas the Hymenoptera, including social insects such as bees, wasps, and ants, are cytoplasm consumers. The cell wall of plants consisting of cellulose, hemicellulose, and lignin is very poor in nitrogen but tends to be abundant and clumped, while cytoplasm is rich in nitrogen but tends to be sparsely distributed. Cellulose, a major component of the plant cell wall, is decomposed to glucose, an important source of energy and body construction for animals. However, cellulose is difficult for most animals to decompose, especially when it is combined with lignin, which is extremely resistant to chemical degradation.

Termites as a whole feed on live and dead vegetation, lichens, algae, fungi, dung, soil rich in organic matter (so-called humus), other individuals of the same colony (cannibalism), organic-rich portion of termite nests, and skins of vertebrate corpses (Wood, 1978). Most termites in natural ecosystems do not attack living plants, although *Microcerotermes* sometimes attacks native living trees in Malaysia and some termites consume living native grasses in savannas and grasslands. Lower termites eat dead wood except Hodotermitidae, which are grass feeders, while higher termites are rich in feeding habits. Some higher termites take specialized food. Some genera of the Nasutitermitinae feed on lichens on tree trunks: *Hospitalitermes* in southeast Asia, *Constrictotermes* in South America, and *Grallatotermes* in east Africa, India, the Philippines, and New Guinea. *Ahamitermes* and *Incolitermes* in Australia and *Ophiotermes* and *Tuberculitermes* in Africa are obligate inquilines in the nest of other termite species and feed exclusively on the carton of nest material of their hosts.

Soil feeders, which are recognized in the Termitinae, Apicotermatinae, and Nasutitermitinae of higher termites, include 1100 species, which is approximately 45% of the described termite species. The development of soil feeding is a landmark in the evolution of termites, considering that it is rare among animals. The real food source for soil feeders is unknown.

Termites are included in the diets of a wide range of animals. Ants are the most dominant predators. They are either obligatory or opportunistic predators. Some ponerine ants, such as *Termitopone commutata* in South America, *Leptogenys chinensis* in Sri Lanka, and *Megaponera foetens* and some subterranean *Dorylus* spp. in Africa, are typical obligate predators. The ant with lethal effects on a termite colony changes with the colony's development. For a colony of the fungus growing termite, *Macrotermes michaelseni* in Kenya, it is opportunistic predatory ants (individual foraging ants such as *Pachycondyla* and *Ophthamopone* and ants with recruitment systems such as *Camponotus* and *Pheidole*) at their early stage, ants with marked recruitment by trail pheromone (e.g., *Megaponera foetens*) at the middle stage, and subterranean group foraging doryline ants (e.g., *Dorylus juvenculus*) at the late stage.

Table 3 Basic similarities and differences in social biology between termites and higher social hymenoptera (wasps, ants, bees)

Similarities	Differences	
	Termites	Eusocial Hymenoptera
1. The castes are similar in number and kind, especially between termites and ants	1. Caste determination in the lower termites is based primarily on pheromones; in some of the higher termites it involves sex, but the other factors remain unidentified	1. Caste determination is based primarily on nutrition, although pheromones play a role in some cases
2. Trophallaxis (exchange of liquid food) occurs and is an important mechanism in social regulation	2. Most species possess soldiers	2. A few species possess soldiers
3. Chemical trails are used in recruitment as in the ants, and the behavior of trail laying and following is closely similar	3. The worker castes consist of both females and males	3. The worker castes consist of females only
4. Inhibitory caste pheromones exist, similar in action to those found in honeybees and ants	4. Larvae and nymphs contribute to colony labor, at least in later instars	4. The immature stages (larvae and pupae) are helpless and almost never contribute to colony labor
5. Grooming between individuals occurs frequently and functions at least partially in the transmission of pheromones	5. There are no dominance hierarchies among individuals in the same colonies	5. Dominance hierarchies are commonplace, but not universal
6. Nest odor and territoriality are of general occurrence	6. Social parasitism between species is almost wholly absent	6. Social parasitism between species is common and widespread
7. Nest structure is of comparable complexity and, in a few members of the termitidae (e.g., <i>Apicotermes</i> , <i>Macrotermes</i>), of considerably greater complexity; regulation of temperature and humidity within the nest operates at about the same level of precision	7. Exchange of liquid anal food occurs universally in the lower termites, and trophic eggs are unknown	7. Anal trophallaxis is rare, but trophic eggs are exchanged in many species of bees and ants
8. Cannibalism is widespread in both groups (but not universal, at least not in the Hymenoptera)	8. The primary reproductive male (the "king") stays with the queen after the nuptial flight, helps her construct the first nest, and fertilizes her intermittently as the colony develops; fertilization does not occur during the nuptial flight	8. The male fertilizes the queen during the nuptial flight and dies soon afterward without helping the queen in nest construction

Source: Modified from Wilson EO (1971) *The Insect Societies*. Cambridge: Harvard University Press.

Mammals that specialize in digging out termite nests are pangolins in Africa and India and armadillos in tropical Africa. Other vertebrates specializing in predation on termite brood centers include armadillo in Texas of the United States, anteaters in South America, sloth bear (*Melurus ursinius*) in India, and the numbat and echidna in Australia. Wild chimpanzees in Africa make and use tools for "fishing" termites (Figure 6).

Nests and Life Types

Termites are ecosystem engineers. They construct nests of various shapes and sizes, sometimes reaching to 5 m in height (Figure 7). The diversity of nests is related to the diversity of social evolution, colony size, and feeding habits as well as the establishment of a microclimate suitable for termites to defend their colony against predators. The inner parts of carton nests of some species contain a large amount of wood fibers, which are eaten by the builders or utilized by inquiline termites. The most remarkable example is fungus gardens of Macrotermitinae.

Nest material has two origins: exogenous material such as particles of soil and wood transported by colony members and fecal. The cohesion of the nest construction is achieved by

saliva moistening of exogenous material. Termites usually use both fecal and exogenous materials for nest construction except for the Macrotermitinae, which do not use fecal material. Soil feeders and arboreal nest builders mainly use fecal material. Soil material is important in most epigeous nests (Abe, 1987).

Three life types are distinguishable in relation to nest and feeding sites: (a) a one-piece type, which nests in a piece of wood and consumes only that piece, (b) an intermediate type, which nests in a piece of wood and consumes it as food but also constructs galleries to consume other wood pieces, and (c) a separate type, which nests in various sites such as on living tree trunks, in soil, on the ground surface, and so on, constructing galleries to consume various dead plant material outside of the nest.

The one-piece type is supposed to be the most primitive. An evolutionary trend of life type is a progressive separation between food and nest. The first step is the development of a subterranean gallery system, which allows the colonization of new wood pieces (intermediate type), and the second step is the distinction of the nest from food (separate type). This change of life types seems to have occurred independently at least three times (Mastotermitidae, Hodotermitidae, and Rhinotermitidae) in the evolution of termites. The one-piece type is observed in primitive lower termites (Termopsidae) and

modern lower termites (Kalotermitidae and *Prorethitermes* of Rhinotermitidae). The Termopsidae usually nest in large damp wood and are called damp wood termites, while the Kalotermitidae usually nest in dry wood of living and fallen trees and are called dry wood termites. *Prorethitermes* of the Rhinotermitidae nest in ordinary wood. In the one-piece type, the size, growth, and longevity of the colony are constrained by the size of a wood piece.

The intermediate type is observed in primitive lower termites (Mastotermitidae) and the modern lower termites (most Rhinotermitidae). The separate type is observed in primitive lower termites (Hodotermitidae), modern lower termites (a few Rhinotermitidae), and the higher termites (Termitidae). Separate type nests are classified into three categories: (a)

subterranean nests constructed below ground, (b) epigeous nests protruding above soil surface, and (c) arboreal nests built on a tree trunk or a tree branch but always linked with soil by covered galleries.

Symbiosis

Digestive Tube

Termite symbiosis is an obligate nutritional mutualism between the termite and microorganisms in the gut and nest of termites, although symbiosis, in the general sense, means the living together of two or more organisms that are not closely related in phylogeny, without the implication of beneficial exchanges.

The digestive organ of lower termites is schematically shown in Figure 8. The digestive tube consists of foregut, midgut tubular (site for secretion of digestive enzymes and for absorption of soluble nutrients), and hindgut (voluminous site for digestion and for absorption of nutrients). The swollen portion of the hindgut is called the paunch. Malpighian tubules, which transport urine and urinary metabolites for excretion, empty at or near the junction of mid- and hindgut. Midgut and salivary glands produce the enzyme for decomposing cellulose into glucose. In the hindgut, cellulose is decomposed into acetic acid by symbiotic flagellates.

The microenvironment becomes more anoxic from foregut to hindgut. The hindgut used to be considered an anaerobic fermentation chamber, but recently this has been found to be false. The hindgut consists of an anoxic lumen surrounded by a microoxic periphery (Figure 9). This is consistent with the occurrence of both anaerobic and O₂-dependent microbial metabolism in the hindgut. Bacteria on or near the gut wall constitute an oxygen sink, consuming the inwardly diffusing O₂ and thereby creating anoxic conditions favorable for

Figure 9 Microenvironment of the hindgut of a termite. Reproduced from Breznak, 2000.

fermentative production of acetate, a major energy source for termites. The hindgut of termites typically has a low redox potential (from -50 to -270 mV) and a pH around neutrality (6.2 to 7.6), although some portions of the hindgut of soil-feeding termites have a pH as high as 11.

Two Types of Symbioses

Woody tissue, a major food of termites, contains only 0.03 to 0.1% nitrogen and their C/N (carbon/nitrogen) ratio is 350 to

500, whereas termite tissues contain 5 to 14% nitrogen and their C/N is 4 to 12. Therefore termites have to solve the "carbon-nitrogen balance" problem in addition to "cellulose decomposition problem" (Higashi *et al.*, 1992). Termites use free-living and symbiotic fungi, gut bacteria, and protozoa for assistance in decomposing cellulose and metabolizing and conserving nitrogenous compounds.

Thus, two symbioses are distinguished in termites: "cellulose decomposition symbiosis" and "C-N balance symbiosis" (Figure 10). All the species of termites are, though to different extents, able to produce their own cellulase. This seems reasonable because they have no way to gain glucose, which is used not only for energy production but also for biological synthesis, other than digesting cellulose for themselves. The lower termites, which harbor symbiotic flagellates, need cellulose decomposition symbiosis to increase the efficiency of cellulose decomposition.

On the other hand, C-N balance symbiosis is necessary for all termites, because they are not able to solve the problem alone. Two mechanisms are possible for C-N balance: adding N to their food, referred to in Figure 10 as route N-1, and selectively outputting C, referred to as routes C-1 and C-2. Termites obtain N either through their food or by fixing atmospheric N. Termites tend to feed selectively on food with above average N content. Some species feed on plant tissue only when it is partially decomposed, and by this means, take advantage of the reduced C/N ratio that results from fungal and microbial decomposition. As selectively eliminating carbon is a "wood-consuming" manner, one-piece type termites, which stay in their wood nest and consume it, are expected to develop mechanisms to add N, such as symbiosis with

Figure 10 A summary (superimposition) of the possible mechanisms for C-N balance, with the responsible symbionts. Black symbols, nitrogen (N); hatched symbols, carbon (C). Reproduced from Higashi M and Abe T (1997) Global diversification of termites driven by the evolution of symbiosis and sociality. In: Abe T, Levin SA, and Higashi M (eds.) *Biodiversity*, pp. 83–112. Springer.

nitrogen-fixing bacteria. On the other hand, separate type termites that are free from the limit in resource utilization are expected to make a full choice among possible mechanisms for C-N balance, including association with methanogenic bacteria. Among the separate type termites, the fungus-growing habit brings additional mechanisms for C-N balance; termites both add N through local N-recycling (route N-2b) and selectively eliminate C through fungal respiration (route C-2).

Cellulose Decomposition Symbiosis

The phylogenetic trend of symbiotic microorganisms in termites and cockroaches is shown in Figure 11. Lower termites harbor flagellates in their hindgut. More than 400 species of flagellates of three orders, Oxymonadida, Trichomonadida, and Hypermastigida, have been described from 205 species of lower termites. Each species of lower termites usually harbors more than one species of flagellates. The class Parabasalea, to which Trichomonadida and Hypermastigida belong, is one of the oldest groups among eukaryotes, lacking mitochondria and peroxisomes. Members of this class use hydrogenosomes for energy production and, like the prokaryotes, have a 70S ribosome.

All colony members of lower termites except eggs, newly hatched larvae, and individuals just after molting harbor flagellates. They are transmitted through proctodeal feeding (i.e., transmission of gut contents from anus of a donor to mouth of a receptor). The flagellates of the mother colony are transmitted to offspring colonies by alates. The paunch of the worker is filled with flagellates and bacteria; they occupy 61% by weight of the hindgut contents of *Reticulitermes flavipes* (Rhinotermitidae). The population of flagellates in a gut of *Reticulitermes speratus* often reaches more than 105 individuals.

Figure 11 Phylogenetic diagram of the termites, in relation to the evolution of symbiosis with protozoans, bacteria, and fungi. Reproduced from Grasse and Noirot, 1959, with some alterations.

The association between lower termites and flagellates is well known, since Cleveland (1924) showed that the lower termite died in 3 to 4 if the flagellates were removed, but reinfection by them enabled their host to survive. However, more than 70% of termite species belong to the Termitidae, which lack symbiotic flagellates. Lower termites in addition to higher termites are more or less able to produce cellulases by themselves. They secrete endo- β -1, 4-glucanases from the salivary gland, while higher termites secrete it from the midgut. The first cellulase gene for the endo- β -1, 4-glucanase was sequenced from a Japanese lower termite, *Reticulitermes speratus*, in 1998.

A biochemical overview of the major processes involved in the symbiosis between termites and their gut microorganisms is shown in Figure 12. The flagellates ingest wood taken by the lower termites and decompose cellulose as follows:

The flagellates provide acetate for termite and bacterial metabolism as well as H_2 and CO_2 for bacterial metabolism.

Cellulose in the plant cell wall is combined with lignin to form lignocellulose. Except for fungus-growing termites, the lignin degradation in termite guts remains ambiguous. Some termites such as *Mastotermes darwiniensis* and *Coptotermes acinaciformis* are incapable of digesting lignin, whereas *Nasutitermes exitiosus* seems to be able to degrade lignin at least in part.

C/N Balance Symbiosis

Lower and higher termites harbor a high density and diversity of bacteria in the gut: 109 to 1011 cells per ml of gut fluid. Most bacteria are distributed in the paunch of the hindgut, but no clear evidence to support a significant role for bacteria in

Figure 12 Biochemical overview of the major processes involved in the symbiosis between termites and their gut microbiota. Reproduced from Slaytor, 2000.

cellulose hydrolysis has been given. Intestinal bacteria are important in nitrogen fixation, nitrogen enrichment of the diet, pyruvate metabolism, or the metabolism or acetogenic reduction of CO_2 .

Carbon elimination through the activities of microorganisms is the most general mechanism of C/N balance. It entails the release of carbon-rich, nitrogen-poor products of digestion leaving an assimilable fraction of digesta enriched in nitrogen. Gaseous forms of carbon released are principally carbon dioxide and methane, which is formed through respiration, fermentation, and methanogenesis. Almost all termites emit methane and soil-feeding termites tend to emit more methane than wood-feeding termites. Diverse prokaryotes are capable of participating in such transformations.

As long ago as 1925, Cleaveland suggested that termites use nitrogen fixation to explain their survival on a diet low in nitrogen. Nitrogen fixation, which is energy demanding, is only known from bacteria. Nitrogen fixation in termites was first reported by Benemann (1973) and Breznak *et al.* (1973). Tayasu *et al.* (1994) estimated the extent of nitrogen fixation in termites by comparing the natural abundance of ^{15}N in termite tissues with that of their food and air, showing that 30 to 60% of the nitrogen in the body of *Neotermes koshunensis* (Kalotermitidae) was derived from N_2 fixation. However, the variation in the importance of nitrogen fixation in the termite colony is not clear.

Nitrogen is conserved by internal recycling of nitrogenous waste from termites, by recycling of feces, or by cannibalism and nectophagy. Nitrogenous wastes excreted into the gut through the Malpighian tubules are broken down by gut microorganisms and recycled. Termites have symbiotic, uricolytic bacteria, which use uric acid as an energy source, producing ammonia as the major end product. Ammonia provides a readily available source of nitrogen for protein synthesis in many bacteria.

Symbiosis with Fungi

Higher plants and animals have developed various symbioses with fungi. The Macrotermitinae of higher termites cultivate the basidiomycete fungus, *Termitomyces*, on fungus gardens (fungus combs) in the nest and are called fungus-growing termites. *Termitomyces* is known only from macrotermitine nests. The fruiting body of *Termitomyces* growing on the comb of *Odontotermes formosanus* at the beginning of the rainy season in Okinawa, Japan, is shown in Figure 13. Ascomycetes of the genus *Xylaria* grow rapidly on the comb, when the comb is removed from the nest.

Fungus-growing habits are known from ants as well (e.g., *Atta*). It is a curious fact, possibly coincidental, that fungus-growing termites, which consume both fungi and fungus combs, are distributed in Africa and southeast Asia, whereas fungus-growing ants, which consume only fungi growing on fungus gardens, are distributed in America.

In *Macrotermes michaelseni* in the grassland of Kenya, old workers (mainly major workers) go out of the nest and collect dead grass pieces. Young workers in the nest consume the pieces and build fungus comb in the mound chambers by depositing fecal pellets of partially digested grass pieces. The comb, which is shaped into round forms resembling brain or sponge, is inoculated with *Termitomyces*, which develop small round white nodules called conidia. Young workers continually deposit the fecal pellets on the top of the comb and consume the conidia, which contain cellulase as well as glucose. Old workers and soldiers consume the old part of the comb from underneath.

The role of *Termitomyces* has been controversial since König and Smeathman discovered the fungus in the 18th century. Suggested roles of the fungus are (a) degradation of lignin in the fungus comb, (b) ingesting and utilization of fungal cellulolytic enzymes in conidia to complement its own digestive

Figure 13 *Termitomyces* (fruit body) growing on the fungus combs of *Odontotermes formosanus* in Okinawa, Japan. Photo by K. Sugio.

enzymes, and (c) improvement of nitrogen economy in termite nutrition.

Termitomyces is able to break down lignin in addition to cellulose in the comb to simpler compounds, which are reingested by old termites together with the fungi. In *Macrotermes mulleri*, a synergistic interaction between the cellulolytic enzyme of the termite and fungal origin in the gut is known, while in *M. subhyalinus* and *M. michaelsoni*, most (90%) of the glucose requirements of workers can be met by the activity of endogenous intestinal cellulases. The extent to which fungal enzymes contribute to cellulose digestion after ingestion by termites is under debate.

The symbiotic fungi seem to be an important nitrogen source for termites, because nitrogen concentration in the fungi is much higher than that in the fungus comb. Thus, all of the three suggested roles of fungus are partly true. The size and morphology of the combs are different among macrotermite species, and the role of fungi may vary among them. The comb plays a role as reserved food for termites, especially at times when food is scarce out of the nest.

Alates of *Macrotermes bellicosus* and *Microtermes* spp. carry the spores of *Termitomyces* in their rectal chamber, while *Ancistrotermes cavithorax*, *A. guineensis*, *Macrotermes subhyalinus*, *Odontotermes pauperus*, and *O. smeathmani* do not carry the fungal spores. They may depend on the source of spores from fungi growing on the soil surface, which the first workers collect.

Social Life

Caste Differentiation

A termite colony usually consists of a pair of reproductives and their offspring including workers or pseudergates (false workers), soldiers, nymphs, larvae, and eggs. Termites are hemimetabolous, and their developmental pathway consists

of several instars with little morphological change until the final molt to alates. The differentiation into castes such as workers, soldiers, and neotenics occurs when immatures deviate from the pathway leading from egg to winged imago (alate). The more evolved the species, the earlier the caste differentiation.

The most important difference in the caste differentiation exists between the one-piece nest type and separate and intermediate nest types. The one-piece type produces pseudergates (false workers), while separate and intermediate types produce workers. The pseudergates, which functionally correspond to workers in separate and intermediate types, retain the capability to be reproductive (alate and neotenic), pre-soldier, and another pseudergate instar. In this sense, pseudergates are helpers.

The developmental pathways of *Kalotermitidae* (*Kalotermitidae* (one-piece type) and *Macrotermes michaelsoni* of *Termitidae* (separate type) are shown in **Figure 14**. *K. flavicollis* is characterized by flexible or late caste differentiation. On the way to the imago, which develops from the egg through seven molts, two irreversible deviations to sterile soldiers and neotenics and one reversible deviation to pseudergates occur. There is no sexual dimorphism: the sex ratio among pseudergates and soldiers usually depart little from 1.

Caste differentiation is controlled by pheromones. Reproductives (king and queen) secrete sex-specific pheromones that inhibit the metamorphosis of immatures into reproductives, although the inhibitory pheromones have not been chemically identified (**Figure 15**). Two inhibitory pheromones are produced by the queen and the king and are passed out of their anuses (proctodeal feeding). When the reproductives die, pseudergates or nymphs molt to neotenics and inherit their parents' colony. The presence of soldiers inhibits the metamorphosis of pseudergates into soldiers, but its physiological basis is not yet known.

The flexible caste differentiation in *K. flavicollis* is associated with its nesting habits. The *Kalotermitidae* to which *K. flavicollis*

Kaloterme flavicollis (Lower termite)*Macrotermes michaelseni* (Higher termite)

Figure 14 Caste development in lower and higher termites. Reproduced from Roisin, 2000.

belongs nest in the dead branches of living trees, standing dead trees, and rarely fallen trees, consuming the wood. Those nests are unstable, because wood consumption by nesting termites leads to nest destruction.

In *Macrotermes michaelseni* of the Termitidae, the second instar is an irreversible decision point separating two developmental pathways to imago and sterile workers and soldiers. The number of larval instars is three in the Macrotermitinae and two in the other Termitidae. A sexual dimorphism frequently occurs in workers, while soldiers are of one sex. In *Macrotermes*, major workers are males and minor workers are females, while major and minor soldiers are females. In *Trinervitermes* of the Nasutitermitinae, soldiers are males and workers are females. Replacement reproductives of the Termitidae arise either from alates and nymphs or workers.

Evolution of Workers and Soldiers

All species of termites, with some exceptional groups in higher termites, have soldiers. They are adapted to living in the darkness and lack compound eyes. The soldiers of most species are sterile, but fertile soldiers that are able to be neotenic are present in *Zootermopsis*, *Archotermopsis* and

Stoloterme of Termopsidae, a family of primitive lower termites.

Soldiers, which are specialized in the defense of nest and foraging workers, are rich in the variety of morphology. Two types can be distinguished; mandibulate and nasute types. Mandibulate soldiers occur in all families and rely on large, prominent mandibles to defend the nest and colony members by biting or snapping with mandibles. In nasute soldiers occurring only in Nasutitermitinae of the Termitidae, the front of the head is modified to chemical warfare and the mandibles are in many cases reduced. Defense by nasute soldiers are very effective to ants, major predators of termites (Figure 16). Soldiers are of one size in most species, but are dior trimorphic in *Schedorhinoterme* of Rhinotermitidae and Termitidae (e.g., *Macrotermes* and *Acanthotermes* of the Macrotermitinae).

The proportion of soldiers to workers (or false workers) in mature colonies varies considerably. Soldiers occupy up to 30% of colony members in the Nasutitermitinae with nasute soldiers, which are usually smaller than workers, while they occupy about 5% in most termites with mandibulate soldiers, which are usually larger than workers. The proportion of soldiers decreases in soil feeders and some of them (mainly Apicotermiteinae of Termitidae) lack the soldier caste.

Figure 15 The pathways of pheromone action in the control of reproductive caste formation in the termite *Kaloterms flavicollis*. In the top row the pair of “crowned” figures represents the reproductives: the functional male (king) to the left and the functional female (queen) to the right. The remaining figures all represent pseudergates. The king and queen produce substances (labeled 1 and 2, respectively) that inhibit transformation of pseudergates into their own royal castes. These inhibitory pheromones are passed directly from the reproductives to the pseudergates and are also circulated indirectly through the digestive tracts of the pseudergates. Another male substance (pheromone 3) stimulates the female pseudergates to change into the reproductive caste, but the reverse relation does not hold. When supernumerary royal males are present, they recognize each other (through pheromone 4) and fight; similarly, supernumerary royal females recognize each other (through pheromone 5) and fight. Finally, royal males stimulate production of pheromone 2 in royal females, and royal females stimulate production of pheromone 1 in royal males; the nature of the stimuli labeled A and B is unknown. Reproduced from Wilson EO (1971) *The Insect Societies*. Cambridge: Harvard University Press.

Workers are numerically the largest caste in the colony and consist of sterile males or females which are wingless, in most cases unpigmented, and lack special external modifications. Compound eyes are usually absent. Workers provide labor for gathering food, feeding dependant castes (larvae, soldiers, nymphs, and reproductives), tending eggs, and repairing and enlarging the nest and gallery system. Worker polyethism is based on age and sex; old workers tend to predominate in outer tasks, while young workers tend to predominate in inner tasks. Workers are of one size in most species, but are dimorphic in some species. Major workers tend to engage in outer tasks, while minor workers tend to engage in inner tasks.

Figure 16 Defensive posture of a worker and nasute soldiers of *Nasutitermes* against an ant worker. Reproduced from Behnke FL (1977) *A Natural History of Termites*. New York: Charles Scribner's Sons.

The presence or absence of sterile castes is shown in relation to life type on the phylogenetic tree in Figure 17. Sterile soldiers appeared earlier than sterile workers, evolved once in one-piece type prototermites with false workers, and disappeared secondarily in some soil-feeding termites. On the other hand, the sterile worker caste has evolved polyphyletically. Separate and intermediate type termites (Mastotermitidae, Hodotermitidae, most Rhinotermitidae, and Termitidae) possess a worker caste, whereas one-piece type termites (Termopsidae, Kalotermitidae, and *Protermitidae* of Rhinotermitidae) possess a false worker caste. The sterile worker may have evolved from the false worker at least three times independently in accordance with the change from one-piece nest to intermediate and separate types.

Diversity in Social Life

The social organization of termites is similar to that of social Hymenoptera in that the colony is organized based on the division of labor due to caste and age. However, there is an important difference between them. In contrast to Hymenoptera, whose active members are imago (adult, which are suppressed to be reproductive), active members such as workers and soldiers of termites are individuals which are suppressed to be imago.

The degree of eusociality, fecundity of reproductives, and the other life history characteristics are diverse among termite species, and they are summarized in relation to life type in Table 4. The reproductive skew, defined as the probability that workers and soldiers forego direct reproduction, is a good indicator of eusociality (0: all colony members reproduce; 1: colony members forego direct reproduction except a single colony breeder). The skew is low in the one-piece type, where pseudergates have the potential to be reproductive, while it is high in the intermediate or separate type, where workers have little chance to become reproductives.

The reproductive skew is negatively correlated with the extent of neotenic production. The percentage of genera producing neotenis is high in the one-piece type (100% in Termopsidae and *Protermitidae* of the Rhinotermitidae) except the Kalo termitidae (48%), medium (100% in Mastotermitidae and 71% in Rhinotermitidae) in the intermediate type, and low (67% in Hodotermitidae and 0–20% in Termitidae) in separate types.

Figure 17 Six families of termites and a summary of their characterization in terms of distribution, nest site, food, symbionts, colony size, life type, and sterile caste. Distribution: Au, Australia; WW, worldwide; Af, Africa; As, Asia; Amp, amphitropical; PT, pantropical. Nest site: W, wood; S, subterranean; E, epigeal mound; A, arboreal. Food: W, wood; DG, dead grasses; DL, dead leaves; S, soil; Li, lichen. Symbionts: P, Protozoa; B, bacteria; F, fungi. Life type: O, one-piece; I, intermediate; S, separate. Sterile caste: S, soldier; W, worker. Reproduced from Higashi M, Abe T, and Burns TP (1992) Carbon-nitrogen balance and termite ecology. *Proc. R. Soc. London B* 249: 303–308.

A remarkable difference among life types is the fecundity of primary reproductives. It is low in the one-piece type, whereas it is sometimes extremely high in the separate type (e.g., a queen of *Macrotermes subhyalinus* lays 36,000 eggs per day).

In comparison with most insects, primary reproductives survive for a long time—10 to 12 years for *Incisitermes minor* (one-piece type) and 20 to 50 years in Macrotermitinae (separate type). It is noteworthy that the longevity of reproductives is similar to that of pseudergates in the one-piece type, whereas it is much longer than that of workers in the separate type.

The age at which termites begin to reproduce is early (beyond the second year in *Kalotermites flavicollis*, beyond the fourth year in *Incisitermes minor*, after the fourth year in *Zootermopsis*, after the sixth year in *Neotermes tectonae*) in the one-piece type, and late (after 5 to 10 years in many species of Rhinotermitidae and Termitidae) in intermediate and separate types. The size of mature colonies producing alates ranges from a few hundred individuals for Kalotermitidae (one-piece type), many thousands or much more in Mastotermitidae, Rhinotermitidae (intermediate type), and Termitidae (separate type).

The colony size is shown in Table 5, although the accuracy of estimation is different. The one-piece type such as the Kalotermitidae and Termopsidae is small, usually up to 10,000, while the separate type such as mound builders of the Termitidae, in particular *Macrotermes* and *Nasutitermes*, is very large up to some millions. The intermediate type, including

the Rhinotermitidae and Mastotermitidae, is sometimes very large up to some millions.

Organization of Foraging

Foraging of termites has evolved in concert with the change of life type. The one-piece type of termites do not forage out of nest, and the nest site selection by alate reproductives plays a role of food research. Dealate reproductives of *Zootermopsis* (Termopsidae) look for a colony founding site in the wood cambium layer containing nitrogen of relatively high concentration.

In intermediate and separate type nesters, a group of workers and soldiers go out of the nest and search for new food sources. Many species show aggressive behavior toward the other colony members of the same or different species, and the foraging territory, which is intra- and interspecifically defended, is known from many termite species.

The division of labor in foraging activities is based on caste and age. Soldiers usually defend foraging workers, and in some species they explore new areas for food and recruit workers to new food sites. Workers mainly collect and process food, and they also defend foraging territory.

Foraging activities are mediated by trail pheromones emitted from the sternal gland. Several substances are isolated from the gland: n-hexanoic acid in Termopsidae, dodecatrienol in Rhinotermitidae, and neocembrene in

Table 4 Distinguishing social characteristics associated with each nest type

Life type:	One piece type	Intermediate type	Separate type
Termite group	Termopsidae, most Kalotermitidae and <i>Protermitidae</i> of Rhinotermitidae	Mastotermitidae, few Kalotermitidae, most Rhinotermitidae and some Termitidae	Hodotermitidae, some Rhinotermitidae and most Termitidae
Reproductive skew*	0–0.5	0.4–0.75	0.7–1.0
Task specializations	Sterile soldiers, false workers and age polyethism	Sterile soldiers, sterile workers and age polyethism	Sterile soldiers, sterile workers and age polyethism sterile soldiers (except in some soil feeders), sterile workers and age polyethism
Fecundity of primary reproductive (eggs/day)	Small <i>Cryptotermes havilandi</i> : 8		Large <i>Odontotermes obesus</i> : 26,000–86,000 <i>Macrotermes subhyalinus</i> : 36,000 <i>Nasutitermes surianamensis</i> : 3,900 <i>Cubitermes severus</i> : 50–600
Age of primary reproductives	Field-observed reproductive 4–5 years in <i>Zootermopsis</i> spp. and 10–12 years in <i>Incisitermes minor</i>	<i>Mastotermes darwiniensis</i> lab-reared reproductives up to 17 years; <i>C. formosanus</i> at least 9 years; <i>R. lucifugus</i> primaries and neotronics up to 7 years in the lab	Primary reproductives 20 years; queens 20–25 years in Macrotermitinae spp. (estimates based on size of physogastric queen)
Age of workers and soldiers	<i>Zootermopsis</i> false workers up to 4 years, soldiers 4–5 years in the lab; <i>Neotermes isularis</i> soldiers and false workers more than 6 years in the lab	<i>Reticulitermes lucifugus</i> soldiers up to 5 years in the lab; <i>R. hesperus</i> workers 3–5 years in the field; <i>Coptotermes acinaciformis</i> workers and soldiers 4 years in the lab	<i>Macrotermes</i> spp. workers and soldiers less than a year in the field and lab; <i>Macrotermes natalensis</i> up to 1.5 year in the lab; <i>Cubitermes ugandensis</i> worker 196–339 days
Colony foundation	A male and female dealate pair	A male and female dealate pair by a cohort of neotronics and workers	A male and female pair (sometimes multiple reproductives) or sociotomy or secondary dealates reproductives, brachypterous neotronics with workers, rarely ergatoid reproductives

Nasutitermitinae of the higher termites. Many chemicals that are not endogenous to termites cause an orientation response. 2- phenoxyethanol from the ink of certain ball-point pens have a trail-following effect on *Coptotermes formosanus*.

Territoriality and elaborate division of labor in foraging were studied well in the Macrotermitinae and the Nasutitermitinae of higher termites, because some species of them forage on the ground. A fungus grower, *Macrotermes michaelsoni* in Kenyan savanna, constructs a large mound and has a very large foraging territory based on subterranean galleries that extend up to 50 m from the mound, run horizontally, and lead to foraging holes on the ground surface. The species possesses four sterile castes, major and minor soldiers, and major and minor workers. Major soldiers mainly defend the mound, while minor soldiers mainly defend foraging workers. Major workers are foraging specialists, while minor workers mainly perform intranidal works. The division of labor between major and minor workers is more or less different among species of *Macrotermes*.

During the night, major workers emerge from the foraging hole, cut off dead grasses, fallen twigs and cow dung on the ground, and bring them into the foraging hole. They form foraging columns (up to 1 m) between the foraging hole and the foraging site, both sides of which are guarded by minor soldiers and rarely major soldiers. The column is attacked by various species of ants. The foraging areas of *Macrotermes carbonarius*, a mound builder in southeast Asia, change irregularly but seem to be arranged to avoid redundant foraging in the long term (Figure 18).

Black marching termites of *Hospitalitermes* of the Nasutitermitinae in southeast Asia form soldier-led foraging columns reaching up to 100 m in length from the nest at the base of trees to feeding sites on standing tree trunks where workers collect lichens. Soldiers explore the feeding site and recruit workers to the feeding site, defending the workers. Three worker castes show division of labor during food collection; minor workers gnaw at lichens and form a food ball that is passed on medium and major workers, which

carry the food ball to the nest. Medium workers also form food balls.

Two arboreal species of Nasutitermitinae, *Nasutitermes nigriceps*, and *N. nigriceps* form a clear foraging territory in a Panamanian mangrove forest. They build arboreal nests and forage along carton-covered tunnels on branches, which radiate from the nest, and have a nonoverlapping foraging area that is intra- and interspecifically defended.

Life History of Fungus-Growing Termites

A new colony is founded by dealates or budding of the parent colony. In most cases, a pair of dealates found a new colony to be primary reproductives. Multiple alate-derived queens are restricted to the Termitidae (ca. 40 species are known). Colony budding is achieved by active migration of swarms containing all castes or by division of a diffusely organized colony.

Figure 18 Daily change of foraging areas and pavement trackways of a fungus-growing termites, *M. carbonarius* in Thailand. Reproduced from Sugio, 1995.

The former, called a “sociotomy,” is known only in the Termitidae (e.g., *Trinervitermes bettonianus*, *T. gratusus*, *Syntermes territus*, and *Anoplotermes* spp.). The latter is known in Mastotermitidae, Kalotermitidae, Termopsidae, Rhinotermitidae, and Termitidae, where the extension of nests is coupled with production of supplementary reproductives.

The life cycle of *Macrotermes michaelseni*, a socially advanced fungus-growing species of the Termitidae in the grassland of Kenya, is shown in Figure 19. After the nuptial flight at the beginning of rainy season, a male (king) and female (queen) pair of dealates form a tandem, dig a small cell in the soil, copulate, and initiate a subterranean incipient colony. Occasionally three or more dealates found a new colony together. The primary queen begins to lay eggs within a few days after mating. They hatch after some weeks.

The first brood is tended by the king and queen and is differentiated into soldiers as well as workers. The first workers begin foraging at about 10th week after colony founding in the fungus grower *Microtomes*. The king and queen are similar in body size at colony founding, but the abdomen of the queen becomes much larger than that of the king with time.

Within a few years, *M. michaelseni* constructs a mound that reaches 3 m in height at the mature stage. A large mound builder has a territory based on subterranean galleries, which

run horizontally in a shallow layer (10–15 cm). Young subterranean colonies can survive within the territories of large mound builders, because they are located at a deeper layer (20–40 cm) than the subterranean galleries of large mound builders and are able to avoid their attack. However, with colony growth they construct foraging galleries in the shallow layer and are killed by large mound builders. Thus in *Macrotermes michaelseni*, large mounds tend to be uniformly distributed due to territoriality, and small (young) mounds are rare in Kenya.

On the other hand, both large and small mounds of *M. bellicosus* are distributed randomly in Nigerian savanna. The mortality rate of large mound builders of *M. bellicosus* is very high due to predation by doryline ants and aardvarks. Thus, young subterranean colonies are not seriously affected by the proximity of mound builders and survive to construct small mounds, which are randomly distributed.

A marked increase in the number of small mounds following the death of large mound-building colonies due to the severe drought has been reported *M. bellicosus* in Senegal and *M. subhyalinus* in Kenya. Thus, when the mortality rate of large mounds is low, they show uniform distribution due to their territoriality, whereas when their mortality rate is high, young mounds are continuously added and mounds as a whole tend to show random distribution. The duration of mound occupation has been poorly understood: 80 years for *Macrotermes* in Africa, more than 100 years for a large mound of *Nasutitermes triodiae* in Australia, and 20 to 40 years for *Amitermes vitosus* in northern Australia.

The Global Diversification of Termites

Major Events in Termite History

Three major events of global diversification that Isoptera has experienced are identified (Higashi and Abe, 1997): (a) the evolutionary radiation of original termites, (b) the expansion and diversification of separate type termites and the diversification of one-piece type termites driven by the expanding separate type termites into fragmented habitats, and (c) the radiation of higher termites.

As stated earlier, Cretaceous fossil species belonging to Hodotermitidae, Termopsidae, and Mastotermitidae are known from Europe, Asia, and North and South America. This shows that primitive lower termites had been globally distributed and diversified in the Cretaceous. Therefore, the first event, the evolutionary radiation of original termites, must have occurred at latest in the Jurassic and Cretaceous periods of the Mesozoic. All living species of Hodotermitidae are specialized in grass feeding, while living species of Termopsidae and Mastotermitidae are wood feeders. Grass feeding habits of the Hodotermitidae must have evolved in the Tertiary period, and Cretaceous Hodotermitidae must have consumed wood, because grasses evolved in the Tertiary.

The fact that the oldest fossil record is the worker of Hodotermitidae is interesting, because this suggests that the evolution of the worker caste occurred in the Mesozoic. We do not know if Cretaceous termites of Hodotermitidae nested in wood or soil.

Figure 19 Life cycle of the fungus-growing termite, *Macrotermes michaelseni*, in the grassland of Kenya. Reproduced from Abe, 1995.

Many fossil species of the Kalotermitidae whose living species are mostly of the one-piece type have been found in the Tertiary period. It is probable that the second major event, the expansion and diversification of separate type termites and the diversification of the one-piece type termites driven by the expanding separate type termites into fragmented habitats, occurred in the Tertiary.

Only a few fossil species of the higher termites are known from the Tertiary. The third event, the radiation of higher termites, may have occurred in the late Tertiary or the Quaternary. On the other hand, the worldwide distribution of higher termites suggests their early evolution and dispersal before the breakdown of Gondwanaland in the Cretaceous. As shown later, it is quite difficult for termites to cross the oceans. It is probable that the radiation of higher termites may have occurred in the late Tertiary or the Quaternary, although the origin of higher termites may be before the breakdown of Gondwanaland in the Cretaceous.

Dispersal Ability of Termites

Islands sterilized by volcanic eruption are good for studying the process of colonization. In 1883, Krakatau, located about 60 km from Java and 40 km from Sumatra, erupted violently and more than half of the island disappeared, leaving the remaining Krakatau and two neighboring islands. The entire flora and fauna of the islands were almost destroyed, but they were rapidly colonized by organisms of Java and Sumatra.

In the Krakatau Islands, three, three, and seven species of termite were collected in 1908, 1919–1933, and 1982, respectively. They were characterized by the dominance of the lower termites (Kalotermitidae and Rhinotermitidae), the one-

piece type, and the absence of soil feeders, although a wood-feeding arboreal species of *Nasutitermes* of the higher termites was found in the Krakatau Islands. On the other hand, the supposed source area (the tip of West Java) was characterized by higher species diversity (13 species), the dominance of higher termites and separate type, and the presence of soil feeders. In the tip of West Java, the one-piece type termites of the Kalotermitidae are confined to the coastal forest, while soil feeders are confined to inner forests.

Alates of termites are specialized for dispersal within a zone of calm air near the ground. The dispersal distances are short in lower termites (up to 300 m) and a little long in higher termites (a few kilometers). It is not impossible but difficult for termites to disperse widely or to reach remote islands by flight. Therefore, termites usually cross the sea by rafting. The Kalotermitidae, the first colonizers, have some preadaptive attributes for oversea dispersal: (a) they tend to be confined to the coastal area and may be easily swept into the sea, (b) they are more tolerant to sea water than other types, and (c) their caste differentiation is flexible.

On the other hand, it is difficult for soil-feeding termites to cross the sea because they have little opportunity to be in rafting wood. Thus the dominance of the Kalotermitidae (one-piece type) and the Rhinotermitidae (intermediate type) in many islands is explained in terms of the differential dispersal ability of termites.

The Evolutionary Radiation of Original Termites

The first event, the evolutionary radiation of the original termites into a new habitat of wood throughout the world, may have been driven by an efficient utilization of wood as an

abundant and stably supplied food resource and nest substrate, which became possible by the evolution of two symbioses for termites (i.e., the cellulose digestion symbiosis with cellulolytic flagellates and the C-N balance symbiosis with nitrogen fixing bacteria). All descendants of the Mesozoic families of Hodotermitidae, Termopsidae, and Mastotermitidae harbor symbiotic flagellates and nitrogen-fixing bacteria in the gut.

Once a termite obtains a means for digestion and C-N balance through association with microorganisms, then wood, which is superabundant but extremely hard to digest and C-N unbalanced, becomes a “well-protected” food resource that can be monopolized by the termite. The diversification of termites into the Hodotermitidae, Termopsidae, and Mastotermitidae together with their worldwide distribution in the Cretaceous may be viewed as an example of niche opening, which often leads to an adaptive radiation.

Conquering the wood habitat should promote the evolution of a false worker caste, because life in a piece of wood causes (a) greater need for concentrating nitrogen, (b) higher possibility of nest succession due to the longer duration time of the nest relative to the longevity of reproductives, and (c) lower possibility of finding an alternative nesting place due to the heterogeneity of resource (wood) distribution. The evolution of this subsociality should further have enhanced the opportunity for eusociality—that is, the production of sterile soldier caste.

Separate Type Expansion and One-Piece Type Diversification

The second major event came with the development of separate type termites, which separate their feeding sites from their nest. They may have expanded, replacing the existing one-piece type termites through a competitive exclusion

process, the detail of which was examined by Higashi and Abe (1997). This is a consequence of asymmetrical competition between one-piece and separate types due to the fact that a piece of wood is food and nest for the one-piece type but only food for separate type termites. On the other hand, some groups of one-piece type termites, which were driven out by the expanding separate type termites into fragmented habitats, should have gone through a diversification process.

This process could be reconstructed based on the present peculiar distribution patterns of one-piece type termites and separate type termites. The three groups of one-piece termites show quite different marginal distribution patterns. Damp wood termites (all species of Termopsidae) show a clear amphitropical distribution (Figure 20). Ordinary wood termites of *Prorethra* are widely distributed in tropical and subtropical regions but tend to be confined to islands. Dry wood termites (Kalotermitidae) are also widely distributed in the tropical and subtropical regions but tend to be confined to dry dead parts of standing trees.

On the other hand, separate type termites, represented by the Termitidae, are widely distributed in tropical mainlands, the central areas of termite distribution. Intermediate type termites, represented by Rhinotermitidae, are widely distributed from tropical to temperate regions. Thus the distribution of the one-piece type and separate type is complimentary, while that of intermediate type covers the ranges of both types.

Although a full explanation of such distribution patterns requires one to take into consideration other factors such as plate tectonics and global change of climate, ecological mechanisms, specifically interspecific interactions and differential dispersal ability, have been a major force in determining the ranges of distribution.

The asymmetrical competition theory predicts that as the latitude (ocean) gets higher (closer), the resource supply rate of the one-piece type increases relative to that of the separate

Figure 20 Distribution of the Termopsidae. Reproduced from Eggleton, 2000.

type, because more wood is available to the one-piece type due to the slower decay rate of damp (dry) wood at higher latitude (seacoast) areas under a given predation pressure. Thus, the one-piece type may compensate its disadvantage from its asymmetrical competition with the separate type and becomes dominant at higher latitude (seacoast) areas. This explains the questioned marginal distribution patterns of damp and dry wood termites. The distribution of ordinary wood termites confined to islands may simply be explained as a result of escape from asymmetric competition due to their dispersal ability.

Separation of feeding site from nest (reproductive site) should enhance the C-N balance symbiosis by adding the option of selective carbon elimination and promoting the evolution of a true worker caste. These should further have enhanced the superiority of the separate type in resource utilization, thus driving the expansion and diversification of separate type termites.

Among the one-piece type termites driven out by the expanding separate type termites, those groups driven into fragmented habitats along seacoasts and islands are expected to have gone through a diversification process. In fact, dry wood termites show a high species diversity as a family.

The Radiation of Higher Termites

The third major event, the radiation of higher termites that are free from flagellates, may have been driven by

the advantage that a termite would have if it could digest cellulose efficiently enough and eliminate cellulosic flagellates, which became possible by eliminating the lignin cover, the major obstacle in cellulose utilization, perhaps through the shift of their diet from wood to a food with less lignin cover.

Those termites that became higher termites must have obtained their own cellulase activity. The present-day termites have their own cellulase activity. What prevents the elimination of cellulosic flagellates from lower termites may be the inefficiency of the termites in cellulose digestion, which should cause the termites a shortage of (not glucose but) energy supply. Thus, cellulosic flagellates are still symbionts to lower termites, though they are not for cellulose digestion but for energy supply. Higher termites are those that succeeded in increasing the efficiency of cellulose digestion to the extent that they no longer need help from cellulosic flagellates for energy supply either. This may be the driving force for their radiation.

For increasing the efficiency of cellulose digestion, the elimination of the lignin cover is expected to be the most effective. An obvious means to achieve the elimination of the lignin cover is to shift the diet from wood to a food with less lignin cover. The nest-food separation makes possible the selection of food. Thus, it is expected that higher termites may appear only from separate type termites, which is indeed the case.

Three major groups of higher termites are recognized: nasute termites (Nasutitermitinae), soil (humus)-feeding

Figure 21 Termites in lowland dipterocarp forest in West Malaysia. Reproduced from Mabberley, 1992.

termites, and fungus growing termites, although there is some overlap among them. They seem to have succeeded in the elimination of the lignin cover.

The Nasutitermitinae show the broadest distribution and the highest species diversity among the higher termites. Their radiation was driven by the evolution of a new type of soldier with a chemical weapon against ants, their major predator, which made it possible to forage out more freely and select food with less lignin cover. The radiation of soil feeders was driven by the shift of diet from wood to humus, which contains less lignin. The radiation of fungus-growing termites was driven by broadening the diet and a new symbiosis with fungi for C-N balance and for lignin reduction.

Termites in Ecosystems

Terrestrial Ecosystems

Terrestrial ecosystems have some characteristics different from aquatic ecosystems—for example, the dominance of the detritus chain among grazing, detritus, and microbial chains; the rare cascading effect of predators on vegetation; the abundance of fungi; and so on. This is partly because vascular plants in terrestrial ecosystems produce lignin, an organic matter extremely resistant to chemical degradation. Plants cover cellulose with lignin to form lignocellulose as a major component of the cell wall. Cellulose is an energy source for many heterotrophs, but its availability decreases markedly when covered with lignin.

Lignin makes it possible for terrestrial plants to support leaves horizontally and transport water from root to leaves and branches, providing various heterotrophs with heterogeneous habitats. Furthermore, lignin regulates the decomposition process of dead plant material, and its remnants play an important role on the formation of humus associated with soil fertility.

Therefore, lignin is a key substance for understanding the architecture and the material flow in terrestrial ecosystems. Considering that microorganisms, especially fungi, are major decomposers of lignocellulose, fungi are reasonably abundant in terrestrial ecosystems, whereas they are poor in aquatic ecosystems that lack lignocellulose.

Brown rot among fungi mainly decomposes cellulose, whereas white rot decomposes both lignin and cellulose. Most soil animals are not able to decompose lignin chemically but decompose it physically and promote the chance of contact between lignocellulose and microorganisms. Termites are distinct among soil animals in that some of them decompose lignocellulose efficiently with the aid of microorganisms in the gut or in the nests.

Many termites live in lowland tropical forests, where 50 to 80 species are found in 1 ha area in Figure 21. Their food is rich in variety including dead branches of living trees, fallen logs, fallen leaves, lichens, and soil. Those termites are functionally largely divided into two groups: soil feeders and litter feeders. Litter feeders are furthermore divided into lignocellulose feeders and cellulose feeders.

Soil feeders, confined to three subfamilies of higher termites, are concerned with the formation of humus associated

with soil fertility. Lignocellulose feeders (fungus growers of Macrotermitinae) decompose both lignin and cellulose rather completely with the aid of the white rot, *Termitomyces*. As they do not leave many lignin remnants, they may functionally well be called giant moving white rot. Cellulose feeders, including most of the other termites, decompose cellulose in dead plant material, leaving lignin remnants. They may functionally well be called giant moving brown rot. Roughly saying, soil feeders, wood feeders, and lignocellulose feeders occupy about 45%, 45%, and 10% of living termite species, respectively.

We do not know what substrates soil feeders really eat. Soil feeders can generally be distinguished from litter feeders by intestinal morphology, the stable isotope ratios of carbon and nitrogen (Figure 22), and by the higher activity of certain gut bacteria, notably methanogens and organisms able to ferment reduced and recalcitrant substrates, including aromatics. An interesting idea that soil feeders eat microorganisms such as bacteria and fungi in ingested soil, and therefore are important members of microbial chain in the tropical forests, is partly supported by the stable isotope analysis and the detection of lysozyme decomposing cell wall of bacteria, but this theory has not been proved.

Figure 22 Plot of mean $\delta^{15}\text{N}$ against mean $\delta^{13}\text{C}$ for the tissues of worker caste termites from the Mbalmayo Forest Reserve, Cameroon. Soil feeders (colonies of eight species, open circles) cluster at the top right and colonies of the wood-feeding *Microcerotermes parvus* (open triangles) at lower left. Species feeding on highly decayed wood (*Cephalotermes rectangularis*; *Termes hospes*) are intermediate. A single fungus grower, *Acanthotermes acanthothorax*, and the wood-feeding *Nasutitermes latifrons* are also shown. Reproduced from Tayasu *et al.*, 1997.

Functional Role of Termites

Taxonomic composition and feeding habits of termite assemblages in some African habitats are shown in Table 6. The species diversity is the highest in the tropical forest and decreases from forests to arid ecosystems. The dominant feeding habits gradually change from soil-feeding to wood- and litter feeding (cellulose and lignocellulose feeding). The species diversity of fungus growers (*Macrotermitinae*) is the highest in slightly dry areas such as savannas and dry forests where soil fungi are poorer than in moist forests. A similar tendency is recognized in tropical forests of southeast Asia.

The change may be explained in relation to the activities of fungi. Soil feeders are abundant and diversified in tropical rain forests where fungi, in particular white rot, may be active and decompose lignocellulose efficiently, decreasing the litter accumulation on the ground. On the other hand, lignocellulose feeders cultivating white rot of *Termitomyces* in the nest chambers with high humidity and temperature are dominant in slightly dry tropical areas where the low humidity may suppress the decomposition of lignocellulose by white rot. Cellulose feeders are widely distributed in areas where fungi may be inactive due to low temperature and inadequate humidity.

Abundance of termites sometimes exceeds 10,000/m² and 10 g wet weight/m², although it is usually up to 4500/m² and 10 g wet weight/m². The biomass of 10 g wet weight/m² is equivalent to 250 persons/km² and 40 kg/person in human beings. In the tropical rain forest of Malaysia where fungus growers are dominant, as much as 30% of the leaf litter supply is consumed by termites. In a Guinea savanna in Nigeria where fungus growers are dominant, termites consume up

to 55% of surface litter. Termites are responsible for up to 20% of total carbon mineralization in the savannas of Africa. Consumption of dead plant material by termites increases when fungus growers are dominant, because they consume five to six times more food per unit of biomass than other termites.

Termites are consumed by a great variety of animals ranging from ants to human beings, forming a large detritus chain. Furthermore, a large number of alates produced by mature termite colonies are eaten by birds and spiders in the canopy, joining the grazing chain of terrestrial ecosystems.

Termites and Soil

While the distribution and abundance of termites are influenced by climatic conditions (air temperature and humidity), soil properties, and vegetation, termites modify local climate conditions, soil properties, and vegetation through the activities of building mounds and excavating subterranean galleries. The effect of termites on soils has been well examined in the textbook *Termites and Soils* by Lee and Wood (1971).

Termites can modify the soil profile by removing soil from various depths (up to 70 m) and transporting it to the ground surface in the form of runways, sheetings, or mounds, from where it is redistributed by water and wind erosion. In central Africa, termites of *Macroterms* form huge mounds up to 10 m in height and 30 m in diameter. Excavation of subterranean galleries has positive effects on the hydraulic conductivity and infiltration rates.

Large mounds built by species of *Macrotermitinae* in Africa and Asia often support a vegetation comprising trees and

Figure 23 Schematic diagram depicting the influence of termites on plant growth. Reproduced from Coventry *et al.*, 1988.

shrubs that is quite distinct from that of the surrounding soils. This difference is considered due to protection from fire, improved drainage, greater soil depth, higher soil moisture, and improved soil fertility. Cation change capacities (CEC), exchangeable cations (Ca, Mg, Na, K), and base saturation decrease with increasing distance from the mound of *Macrotermes michaelseni* in the grassland of Kenya and available phosphorous and NO_3^- nitrogen are high near the mound. This causes the change of vegetation; maximum standing stock of plants occurs near the mound base and the number of plant species increases with increasing distance from a mound. **Figure 23** shows a schematic diagram depicting the influence of termite mounds on plant growth.

The termite mound supports a higher level of bacterial activity than adjacent top soil, especially of cellulose decomposers, and the activities of these microorganisms result in the release of nutrients into the mound soil. Many species of higher termites have developed to store the fragments of grasses and leaves in the mounds mainly in somewhat dry regions. The stored fragments are heavily colonized by microorganisms. The storage chambers may have the specific function of decomposition chambers and the process may be similar to the fungus gardens of the Macrotermitinae in that it provides the colony with organic material enriched in nitrogen.

Termites and Human Disturbances

The abundance and species diversity of termites tend to decrease when tropical forests and savannas are cleared and modified (**Table 7**). At first soil feeders are replaced by fungus growers and then by wood feeders in Africa and Asia. However, the destruction of natural ecosystems and their replacement by other ecosystems in some cases provides suitable habitats for some groups of termites, leading to an increase in their population. Zimmerman *et al.* (1982) were the first to draw attention to the topic in relation to the production of greenhouse gas by termites.

The global concentration of atmospheric methane, a greenhouse gas, is increasing in recent years at an annual rate of about 1%. This has been mainly attributed to paddy rice cultivation, enteric fermentation (mainly by ruminants), biomass burning, and fossil fuel consumption. Termites have high biomass and emit methane in many tropical ecosystems.

Much research has been done on the global estimates of termites, methane production by various groups of termites, oxidation of methane produced by termites in the soil, and the importance of methane production by termites on global climatic change. The rate of emission of methane by termites differs between species and feeding habits. Soil feeders tend to produce more methane than wood feeders on a

biomass-specific basis. An important fact is that a large amount of methane produced by subterranean termites is oxidized by microorganisms in the soil. Thus the annual contribution by termites is estimated to be less than 20 Tg and probably less than 10 Tg (ca. 4% and 2% of global total from all sources, respectively).

Termites usually consume dead plant material and do not attack living plants in natural forests. However, some termites that are able to survive in agricultural ecosystems become harmful to crops (Harris, 1971). This tendency is stranger when the crops are exotic. A few hundred species of termites cause damage and only about 50 species are serious pests (Pearce, 1997).

Glossary

Ctenidia (*ctenidium sing.*) The molluscan gill, comprising a characteristic muscular axis from which multiple filaments arise. The relative placement of ciliary bands, nerves, muscles, and blood spaces is similar in all extant taxa.

Mantle An ectodermal tissue layer that secretes calcium carbonate in the form of spicules or shell.

Radula A ribbon-like structure bearing transverse rows of small “teeth,” typically used to collect food and move it into the mouth.

Torsion The 180° counterclockwise rotation of the visceral mass and mantle cavity during the larval stage of gastropods.

Introduction

The molluscan body plan typically consists of four body components: (1) a head with tentacles and eyes, (2) a ventral muscular foot, (3) a dorsal visceral mass, and (4) the enveloping mantle that secretes the shell. A space between the covering mantle and the side of the foot forms a mantle (or pallial groove). In most molluscs the groove deepens in the posterior region to form a cavity that contains a pair of gills, or ctenidia, as well as openings of the rectum, paired renal organs, and gonads.

The mouth typically is equipped with jaws and a radula. Numerous glands and sacs are associated with the mouth (or buccal chamber) and esophagus, which opens into a stomach. A digestive gland also opens into the stomach. The hindgut, or intestine, is typically long and highly looped or coiled. The nervous system is concentrated in the head and consists of four ganglia—cerebral, visceral, pedal, and pleural. They are connected by commissures; the paired pedal nerve cords extend ladder-like through the foot. The circulatory system consists of a heart enclosed within the pericardium. The heart has multiple auricles and a single ventricle. The system is typically open except in cephalopods, which have capillaries. The excretory system is paired and connected to the pericardium as well as the gonads in some taxa. The gonads are also paired, but can be fused into a single structure (Polyplacophora) or reduced to a single organ (Gastropoda). Separate gonoducts are present in some taxa, and in other taxa the gonads empty into the kidneys. These connected, mesodermal structures (pericardium, kidneys, and gonads) likely represent the reduced coelom of the Mollusca.

The characters that diagnose the Mollusca are a shell-secreting mantle with a tripartite mantle edge divisible into outer, middle, and inner folds; the secretion of an outer proteinaceous layer, or periostracum; the secretion of multiple crystal types and arrangements (microstructures) within the shell; and a pericardium. Plesiomorphic characters include a mantle groove with flow-through water current patterns, bilateral symmetry, and cephalic tentacles.

This body plan has been substantially modified both among and within groups. Diversification appears to have occurred very early in the history of the Mollusca, but there has been surprisingly little change in some groups. For example, the shells of late Cambrian monoplacophorans are almost identical to those of living taxa despite 450 million years of evolution. Other examples of little change include protobranch bivalves, nautiloids, and scaphopods. There have also been some large and notable extinctions, including those of the bellerophonoids, hyoliths, rostroconchs, and ammonites.

Temporal and Spatial Distributions

The Mollusca include some of the oldest metazoans found in the fossil record. Late Precambrian rocks of southern Australia and the White Sea region in northern Russia contain bilaterally symmetrical, benthic animals with a univalved shell (*Kimberella*) that resembles those of molluscs in many respects. The earliest unequivocal molluscs are found in the early Cambrian, and there is even some support for a Precambrian presence (Coeloscleritophora). Most of the familiar groups, including gastropods, bivalves, monoplacophorans, and rostroconchs, all date from the early Cambrian, whereas cephalopods are first found in the middle Cambrian, polyplacophorans in the late Cambrian, and the Scaphopoda in the middle Ordovician. Most of these taxa tend to be small (<10 mm in length). After their initial appearances, taxonomic diversity tends to remain low until the Ordovician, when gastropods, bivalves, and cephalopods show strong increases in diversity. For bivalves and gastropods this diversification increases throughout the Phanerozoic, with relatively small losses at the end-Permian and end-Cretaceous extinction events. Cephalopod diversity is much more variable through the Phanerozoic, whereas the remaining groups (monoplacophorans, rostroconchs, polyplacophorans, and scaphopods) maintain low diversity over the entire Phanerozoic or became extinct (Figure 1).

Figure 1 Spindle diagrams of the relative diversity of major molluscan groups through time. (Valentine, James; *Phanerozoic Diversity Patterns*, Copyright © 1985 by Princeton University Press. Reprinted by permission of Princeton University Press.)

Molluscs occur in almost every habitat found on Earth. Large concentrations of gastropods and bivalves are found at hydrothermal vents in the deep sea, whereas other gastropods live above tree line in Arctic tundra and on mountain slopes. Molluscs occur in the wettest environments of tropical rain forests and in the driest deserts, where annual activity patterns may be measured in hours. They live below ground in the lightless world of aquifers and caves, and even interstitially in groundwater (stygobionts), but are also familiar organisms of the seashore, rivers, and lakes and even our gardens. The only thing molluscs do not do is fly, unless the passive aerial dispersal of minute land snails among the Pacific Islands by high winds is considered to constitute flying.

Like many other organisms, marine molluscs reach their highest diversity in the tropical western Pacific and decrease in diversity toward the poles. Marine diversity is also highest nearshore and becomes reduced as depth increases beyond the shelf slope. In terrestrial communities gastropods can achieve great diversity and abundance: as many as 60–70 species may coexist in a single habitat and abundance in leaf litter can exceed more than 500 individuals in 4 liters of litter. Abundance and diversity for some groups can also be higher in temperate communities than in tropical settings. In freshwater communities, species diversity tends to be lower but abundances of sessile molluscs such as the zebra mussel *Dreissena polymorpha* can exceed more than 3000 individuals per square meter.

Major Groups

The major groups of living molluscs are clearly dissimilar from one another and have long been recognized as distinct taxa. However, not all were originally recognized as belonging to the Mollusca. For example, the worm-like bodies of the aplousobranchs were perplexing to early biologists and required study of their internal anatomy to ultimately recognize their affinities with the other molluscan groups. This problem becomes especially acute with fossil taxa; the extinct groups (indicated with a dagger) discussed below may or may not be molluscs in our current delimitation of the taxon based on living representatives. However, there is little doubt that at

Figure 2 Articulated halkieriid from the early Cambrian of Greenland. (Peel, J. S.; *Functional morphology, evolution and systematics of Early Paleozoic univalved molluscs*. Bulletin Grønlands Geologiske Undersøgelse 161. Copyright © 1991 by Geological Survey of Greenland. Reprinted by permission of Geological Survey of Denmark and Greenland.)

some more inclusive grouping these fossil taxa share common ancestors with living molluscan groups.

The converse problem obtains for living taxa. For example, whereas it is possible to relate living taxa to one another using both morphologic and molecular characters, there exists the real possibility that the living taxa do not share a single most recent common ancestor, but may have had multiple, independent derivations from distantly related molluscs or mollusc-like taxa that are now extinct (see below). These alternatives require that both fossils and living taxa be studied and incorporated into evolutionary scenarios and hypotheses of molluscan relationships, especially when the fossil record provides such a wealth of fossils and putative relatives.

Coeloscleritophora†

The worldwide presence of small, hollow, calcareous sclerites in numerous Precambrian and Cambrian sediments (collectively referred to as “small shellies”) was an enigmatic component of molluscan evolutionary studies. However, in the early 1990s, an articulated fossil was found in the lower Cambrian of Greenland that was covered with small shellies. It was immediately apparent that what had been thought to be the remains of individual organisms were actually parts of a single larger animal (Figure 2). Recent work in the Cambrian of Europe, Asia, and Australia has greatly expanded our knowledge of Coeloscleritophora, and although their relationship to the Mollusca remains uncertain, they likely share a common ancestry with the molluscs as well as with annelids and brachiopods.

Hyolitha†

Hyoliths (Figure 3) had cone-shaped shells with a (presumably ventrally) flattened side. The aperture was closed by

Figure 3 The hyolith, *Haplophrentis carinatus*, middle Cambrian. (Briggs, D. E. G., D. H. Erwin, and F. J. Collier; The Fossils of the Burgess Shale, Copyright © 1991 by Smithsonian Institution. Reprinted by permission of Smithsonian Institution Press.)

Figure 4 Rostroconchia. Top, *Conocardium* sp., Carboniferous. Bottom, *Pinnocaris* sp. Ordovician.

an operculum, and a single pair of anterior appendages (or Helens) is present in some taxa. The operculum was attached to the shell by pairs of symmetrical muscles. Shells were constructed of crossed lamellar calcium carbonate crystals, and the apical tips bore larval shells. Two forms of larval shells—a smooth globose shell and a point shell with growth lines—perhaps reflected direct and indirect development, respectively. A looped alimentary system connected the ventral mouth to the dorsal anus. Hyoliths were sessile, epifaunal deposit feeders, scrapping sediments from the seafloor. They first appear in the early Cambrian and became extinct at the end of the Paleozoic.

Rostroconchia†

Rostroconchs (Figure 4) begin life with a single conch (or valve), but the single shell transforms ontogenetically into a nonhinged bivalved shell that gapes at its margins. Based on muscle scar patterns, the animals appear to have had anterior feeding tentacles that were likely used for deposit or suspension feeding, and both motile and nonmotile forms have been recognized. Rostroconchs first occur in the lower Cambrian and undergo an extensive late Cambrian and early Ordovician radiation. The last known rostroconchs occur in the Permian. Rostroconchs are thought to share common ancestry with the Bivalvia.

Polyplacophora

Polyplacophoran molluscs, or chitons (Figure 5), have a dorsal shell that is secreted as eight valves or plates. The plates of individual animals differ in size and shape based on their sequential position; this plate dimorphism is also present in the earliest chitons of the late Cambrian. Although known

Figure 5 External morphology of the Polyplacophora. Left is dorsal view, right is ventral view. Modified from Gray, Maria; Figures of molluscous animals, selected from various authors. 1857–1859. Reprinted with permission from Gray, Maria.

since the early Paleozoic, chitons do not show a marked increase in diversity until the Cretaceous. Chitons occur worldwide in intertidal habitats and at depths in excess of 7000 m. There are about 850 species and they live on a variety of firm substrates ranging from rocks to algae.

Shell plate morphology has been an important character in determining taxa and relationships. The plates are composed of two distinct shell layers. The outer surface of each plate is high in organic content layer and overlies an inner calcareous layer. Plates may be covered by a thin periostracum. The posterior and anterior edges of each plate have projecting flanges and slits for articulation with other plates, and the outer surfaces are sculptured into distinct regions. The outer plate layer is penetrated by numerous vertical canals that connect to the mantle edge via a canal system that lies between the outer and inner layers. The canals come in two sizes and connect sense organs (including eyes) on the dorsal surface of the valves with the mantle's nervous system.

The plates are surrounded by the girdle, which is formed by a strongly differentiated mantle epidermis. The mantle secretes the plates and surrounds their articulated form. Around the outer plate boundaries the mantle epidermis becomes thicker and secretes a vast array of scales, spines, bristles, and other structures on its dorsal surface. In some species the anterior portion of the mantle epidermis is modified into a large hood that is used to trap food; most species feed by grazing on hard substrates. A poorly defined head and elongated foot that is surrounded by the ventral mantle epidermis of the girdle mark the ventral surface of the animal. The gills are located in the mantle groove that is formed between the girdle and the lateral sides of the foot. The excretory pores and gonoducts also open into this groove.

The visceral mass of the chiton is dominated by a long looped alimentary system. Above the digestive system is a bilobed gonad that appears to result from the fusion of a single pair of gonads. Two separate gonoducts lead from the gonads to opposite sides of the mantle groove. The excretory organs are paired and each connects with the pericardial cavity via a short canal. The center of the pericardial cavity contains an elongated ventricle that is surrounded on either side by enlarged auricles that collect blood from the lateral gills. The polyplacophoran nervous system is ladder-like and almost identical to that of the aplacophorans and monoplacophorans; however, it differs from both by lacking cerebral ganglia. The radular musculature is also similar to that of the monoplacophorans, and the radular tooth configuration is

docoglossate like that of the monoplacophorans and patellogastropod limpets. The typical chiton radula has a weak central tooth that is flanked by strong lateral teeth and weaker marginal teeth, some of which are only plates.

Chiton development has been well studied. The larvae come from relatively large eggs and are nonfeeding. The eggs are covered by a thick hull with elaborate spines and knobs. The chiton embryo hatches as a trochophore, a globular cell mass with an apical tuft and central band of cilia, and subsequently elongates and differentiates into a small chiton. Larval eyes are present but disappear after settlement. The most marked external development is the formation of the foot on the ventral surface of the larva and the formation of transverse bands on the dorsal surface of the larva that mark the sites of valve formation. As the valves form, the apical tuft and prototroch are lost.

Aplacophora

The morphological distance between an aplacophoran mollusc (Figure 6) and, for example, a cephalopod mollusc stretches anyone's concept of the rank of phylum. Aplacophora were the last class to be placed in the Mollusca and have until recently been one of the least studied groups. The aplacophoran molluscs include two different morphological groups: the Chaetodermomorpha or Caudofoveata, and the Neomeniomorpha or solenogastres. The Chaetodermomorpha are footless vermiform molluscs that live in sediments. The Neomeniomorpha are more elongate, have a narrow foot, and typically live in association with cnidarians such as hydroids and alcyonaceans. They are found throughout the world and live at depths between 18 and 6000 + m. It is estimated that there are about 250 species of aplacophorans.

The shell of the aplacophoran mollusc is a myriad of calcareous spicules that are secreted by the mantle epidermis. Spicule morphology varies over the body of the aplacophoran, and in some taxa spicules are modified into scales.

The calcareous spicules that cover the bodies of most aplacophorans give the animals a striking sheen. In the Neomeniomorpha there is a pedal groove on the ventral surface of the animal. The pedal groove expands into an anterior pedal pit and contains the narrow foot. The Chaetodermomorpha lack a pedal groove but do have a posterior mantle cavity that contains a gill. In some Chaetodermomorpha there is a slight constriction and distinct change in spicule morphology at the midline of the body.

It is the internal anatomy that provides evidence of the molluscan identity of the aplacophorans. In both groups the anterior end of the alimentary system includes a radula and odontophore. In the Chaetodermomorpha the radula and odontophore are strongly developed, and the alimentary system is more differentiated than in the Neomeniomorpha. Both groups have a dorsal gonad that opens into the pericardium, which contains the heart. From the posterior portion of the pericardium there extends a coelomoduct that loops or bends and ultimately opens into the mantle cavity. In the Neomeniomorpha the posterior portion of the coelomoducts are modified for reproductive functions such as sperm storage or brooding young. The nervous system is ladder-like with a

Figure 6 External morphology of a chaetodermomorph Aplacophora. (Redrawn from Scheltema, 1985, *Biological Bulletin*, 169:496, Figure 3L. Reprinted by permission of the author.)

well-developed cerebral ganglion. Radular configurations are quite variable and show a wide range of tooth development and modifications that include jaw-like structures, denticles with cones, and sweepers. This is one of the greatest ranges of radular variation found in a Mollusca, and it stands in marked contrast to the lack of variation in the radular configurations found in both the Monoplacophora and Polyplacophora.

Development of the aplacophoran mollusc includes a test cell larval stage in which the three tissue types (mesoderm, ectoderm, and endoderm) align and differentiate within an exterior cell layer constructed of large test cells. Aplacophoran eggs are relatively large and free-spawned in the Chaetodermomorpha and fertilized internally in the Neomeniomorpha; some Neomeniomorpha brood their young to various stages of development. After the formation of the test cell larva with an apical tuft and prototroch, the posterior development of the differentiating larva quickly outgrows the constraints of the exterior test and develops directly into the juvenile aplacophoran.

After many years without students, the Aplacophora are now the subject of extensive studies. These studies and interpretations of aplacophoran phylogeny have focused attention on this small group of molluscs. Overall, the aplacophoran body plan is very similar to that of the chiton. Aplacophorans and polyplacophorans differ from the monoplacophorans by having a dorsal gonad rather than a posterior gonad. The pericardium is similar in all three groups as are many of the other organ systems and positions. Major differences are found in the type of shell secreted by the dorsal mantle epidermis.

Bivalvia

Bivalves (Figure 7) are laterally compressed molluscs with a hinged, two-part shell. A noncalcified ligament serves as a hinge and connects the two valves along their dorsal surfaces and acts to force the valves apart. The remaining shell surfaces may tightly close or gape with contraction of the musculature. Adult valves can vary greatly in shape and size and certain shell forms appear associated with specific habitats. The shell can be internal and reduced (or even absent) and the bivalve animal worm-like such as in "shipworms" (*Teredo*). Although the first occurrences of taxa referred to the Bivalvia are found in lower Cambrian deposits, it is not until the lower Ordovician that bivalve diversification, both taxonomic and ecological, explodes in the fossil record. This diversification continues unabated through the Phanerozoic, with relatively small losses at the end-Permian and end-Cretaceous extinction events. Today over 10,000 species of bivalves are found in most marine, brackish, and freshwater communities. They

Figure 7 External morphology of the Bivalvia. Modified from Gray, Maria; Figures of molluscos animals, selected from various authors. 1857–1859. Reprinted with permission from Gray, Maria.

may be infaunal or epifaunal, and epifaunal taxa may be either sessile or motile. Bivalves typically display bilateral symmetry both in shell and in anatomy, but there are significant departures from this theme in taxa such as scallops and oysters.

Bivalve shells are constructed of different shell fabrics, including crossed lamellar, nacreous, and foliated microstructures. Most of the variability in shell structure sorts along higher taxon divisions. For example, nacreous structures are present primarily in the basal members of the group (Protobranchia) whereas crown taxa have primarily crossed lamellar shells (Heterobranchia). The outer shell surface is often covered by a periostracum, and the free margins of the shell of some taxa may be uncalcified and flexible. In some taxa such as oysters, one valve is cemented to the substrate. The hinge area often contains an array of sockets and pegs, referred to as “teeth” or hinge dentition. These teeth align the valves as they close and prevent shearing of the valves. The inner surfaces of the valves have scars formed by the adductor shell muscles, typically positioned in the anterior and posterior regions and connected by the pallial line that marks the ventralmost attachment point of the mantle.

The mantle that envelops the bivalve animal forms a large ventral chamber or mantle cavity with paired ctenidia. The mantle edge along the posterior portion of the shell often forms a pair of siphons that facilitate inflow and outflow of water through the mantle cavity. Although the pleisomorphic feeding state for bivalves is likely deposit feeding, the ctenidia provide an effective filter-feeding mechanism in most taxa with numerous levels or grades of organization. Bivalves lack a well-defined head and a radula. The foot is often triangular and in some species, such as mussels, the larval byssal gland is retained into the adult and attaches the individual to the substrate with strong fibers.

The visceral mass is primarily situated above the mantle cavity and continues ventrally into the foot. The mouth is often flanked by palps and opens into a stomach. The intestine is irregularly looped and opens dorsally into the excurrent flow near the exhalant siphon. Also opening into this region are the paired kidneys and, when separate from the kidneys, the gonopores of the paired gonads. The heart typically lies below the center of the valves and consists of two auricles and a single ventricle that supplies both anterior and posterior

aorta. The nervous system is made up of three pairs of ganglia. These innervate the musculature, mantle, viscera, ctenidia, and siphons. They receive sensory input from statoliths, osphradium, various siphonal sensory structures, and photoreceptors along the mantle margin.

Bivalve development has been well studied, primarily because of the economic importance of bivalves (see below). The eggs are typically small and not very yolky. Fertilization is usually external, but in brooding species occurs in the mantle cavity. Cleavage patterns are spiral and both polar lobes and unequal cleavage patterns are present throughout the group. The first larval stage is typically a trochophore that transforms into a veliger. Although morphologically similar to the gastropod veliger stage, phylogenetic analyses suggest that these larval stages are homoplastic rather than homologous. The initial uncalcified shell grows laterally in two distinct lobes to envelop the body. Larval bivalves have a byssal gland that may assist with flotation while planktic but later attaches the juvenile to the substrate.

Monoplacophora

For more than 50 years the Monoplacophora (**Figure 8**) were known only from the fossil record and were recognized by the presence of multiple, symmetrical muscle scars in patelliform shells. The discovery of living monoplacophorans, beginning with *Neopilina galatheae* in 1957, provided anatomical characters for the group. About 20 living species of monoplacophorans have since been discovered worldwide, living at depths between 174 and 6500 m. They are found both on soft bottoms and on hard substrates on the continental shelf and seamounts. Paleozoic taxa are associated with relatively shallow water faunas (> 100 m).

In Recent and fossil patelliform monoplacophoran shells, the apex is typically positioned at the anterior end of the shell, and in some species actually overhangs the anterior edge of the shell. Aperture shapes vary from almost circular to pear-shaped. Shell height is also variable and ranges from relatively flat to tall. Shell sculpture varies from rugose concentric ridges to fine growth lines. In some taxa radial sculpture produces a fine reticulate pattern.

The monoplacophoran animal has a poorly defined head with an elaborate mouth structure on the ventral surface. The mouth is typically surrounded by a V-shaped, thickened anterior lip and postoral tentacles; postoral tentacles come in a variety of morphologies and configurations. Below the head

Figure 8 External morphology of the Monoplacophora. Left is dorsal view, right is ventral view. (Reprinted by permission from Nature (179:413–416), copyright 1957 Macmillan Magazines Ltd.)

lies the semicircular foot. In the mantle groove, between the lateral sides of the foot and the ventral mantle edge, are found five or six pairs of gills (less in minute taxa).

Internally, the monoplacophoran is organized with a long, looped alimentary system, two pairs of gonads, and multiple paired excretory organs (four of which also serve as gonoducts). A bilobed ventricle lies on either side of the rectum and is connected via a long aorta to a complex plumbing of multiple paired atria that in turn are connected to the excretory organs. The nervous system is ladder-like and has weakly developed anterior ganglia; paired muscle bundles enclose the visceral mass. The most interesting anatomical structures in the original description of a living monoplacophoran were the paired "dorsal coeloms" that are connected to the anterior excretory organs and are topographically similar to the fused gonads in chitons. Later studies suggest that these structures are more likely extensions of glands associated with the pharynx. The monoplacophoran radula is docoglossate: it has a rachidian tooth, three pairs of lateral teeth, and two pairs of marginal teeth. The lateral teeth are in a stepped configuration: the first and second pairs of lateral teeth are aligned with the rachidian tooth, and the third lateral pair is slightly posterior and lateral to the first two pairs. The cusp of the innermost marginal tooth is frilled.

Developmental studies of monoplacophorans have not been done.

Recent monoplacophorans form a distinct clade, and their similarities and differences with the other extant molluscan groups are easily recognized. There is little question that some Paleozoic taxa also are members of this clade. However, the characters that distinguish some Paleozoic monoplacophorans from torted molluscs (i.e., the Gastropoda) and vice versa are open to alternative interpretations, and the relationships of several major groups of early-shelled molluscs have therefore been the subject of much lively debate.

Scaphopoda

The scaphopod mollusc (**Figure 9**) combines gastropod-like shell morphology with bivalve-like development with cephalopod-like anatomy. Members of the class first appear in the early Paleozoic and the taxon has maintained a slow and steady rate of increase in morphological diversification since then. Our knowledge of the biology of recent species comes primarily from members of a single genus, *Dentalium*. Scaphopods are infaunal organisms and feed on foraminiferans and other interstitial prey. Approximately 350 species occur

from the intertidal zone to depths in excess of 7000 m and are present in all the major oceans.

The scaphopod shell is a calcium carbonate tube with equal or unequal apertures; the tube may be either inflated or bowed. The shell microstructure includes prismatic and crossed-lamellar components; the latter is similar in structure to elements seen in members of the Bivalvia.

The head and foot extend through the ventral aperture of the scaphopod shell. The head bears numerous tentacles (captaculae) that are used to capture and manipulate prey. Foot morphology is variable and has been used as a taxonomic character. The pattern of water circulation through the scaphopod mantle cavity is also unique among the molluscs, because water both enters and exits through the small dorsal aperture. Scaphopods also lack gills.

Unlike the previously discussed groups, scaphopods have a U-shaped gut rather than an anterior–posterior configuration of the mouth and anus. The stomach and digestive gland are in juxtaposition, and the intestine loops before passing through the excretory organ and opening into the mantle cavity. The posterior portion of the digestive gland overlies the gonad that connects with the mantle cavity via the excretory organ. There may be a reduced pericardium, but a heart is absent. The radula consists of a rachidian plate, a single first lateral tooth, and a lateral plate.

The ontogeny of several species has been documented. The trochophore larva has an apical tuft and prototroch and develops mantle folds that divide the larva into equal lateral halves. A velum forms from the prototroch on the anterior end and the dorsal and lateral sides of the larvae begin to secrete a shell that fuses along the ventral surface of the larva but leaves an opening at the posterior end. The trilobate foot forms ventrally under the velum, and the larva attains the tubular shell morphology of the adult scaphopod. The loss of the velum and completion of organogenesis after settling complete metamorphosis.

Scaphopods have an intriguing set of molluscan characters that have been allied to several scenarios of molluscan evolution and relationships. Their shell structure and development suggest bivalvian affinities, but scaphopods also have a radula. The gross morphology of the scaphopod gut is U-shaped, like that of the gastropods and cephalopods, rather than linear as in monoplacophorans, polyplacophorans, and aplacophorans. However, like monoplacophorans, scaphopods have a gonad that lies under the alimentary system rather than on top of it as in aplacophorans and polyplacophorans. Some workers have suggested that aplacophoran larvae and scaphopod larvae share some features; however, others are unconvinced by these arguments and compare the scaphopod velum to that of higher bivalves.

It has been suggested that scaphopods are descended from ribeiriid rostroconchs and they have been grouped with the Bivalvia. Though there is little doubt that scaphopods share some characters with the Bivalvia, the direct derivation of the scaphopod mollusc from a ribeiriid rostroconch is contradicted by the U-shaped gut present in scaphopods. Rostroconchs are thought to have had a linear gut. Thus, the transition from the ribeiriid condition to a scaphopod morphology would include the construction of a U-shaped alimentary system from a linear one, although the ancestral linear gut would have been an ideal

Figure 9 External morphology of the Scaphopoda. Modified from Gray, Maria; Figures of molluscos animals, selected from various authors. 1857–1859. Reprinted with permission from Gray, Maria.

exaptation for a scaphopod shell morphology open at both ends and with flow-through water circulation. Like many other characters, novelties and confusing patterns are common in molluscan morphology but so are convergent grades (especially in molluscan shell form).

Gastropoda

Externally, gastropods (Figure 10) appear to be bilaterally symmetrical; however, they are one of the most successful clades of asymmetric organisms known. The ancestral state of this group is clearly bilateral symmetry (e.g., chitons, cephalopods, bivalves, see above), but gastropod molluscs twist their organ systems into figure-eights, differentially develop or lose organs on either side of their midline, and generate shells that coil to the right or left. And although they have left the more common molluscan state of bilateral symmetry, gastropod molluscs are one of the most diverse groups of animals, both in form and habitat. They occupy habitats ranging from the deepest ocean basins to the highest mountains and from the tropics to high latitudes. Estimates of total extant species range from 40,000 to over 100,000, but may be as high as 150,000, with about 13,000 named genera for both Recent and fossil species. They have figured prominently in paleobiological and biological studies, and have served as study organisms in numerous evolutionary, biomechanical, ecological, physiological, and behavioral investigations. They have a long and rich fossil record that shows periodic extinctions of subclades, followed by diversification of new groups.

The best documented source of gastropod asymmetry is the developmental process known as torsion. Like other molluscs,

gastropods pass through a trochophore stage, and then form a characteristic stage of development known as the veliger. During the veliger stage a 180° rotation of the mantle cavity from posterior to anterior places the anus, and renal openings over the head, and twists organ systems that pass through the snail's 'waist' (the area between the foot and visceral mass) into a figure eight. This rotation is accomplished by a combination of differential growth and muscular contraction. In some taxa the contribution of each process is about 50:50, but in other taxa the entire rotation is accomplished by differential growth. Although the results of torsion are the best known asymmetries in gastropods, numerous other asymmetries appear independent of the torsion process. Anopodal flexure, sometimes considered a feature of torsion, is widely distributed in the Mollusca; it is present in the extinct hyoliths as well as in the Scaphopoda and Cephalopoda (and to a lesser extent in the Bivalvia).

Trends in gastropod evolution often feature a reduction in the complexity of many characters. These include reduction of the number of radular teeth, simplification (thought to be due to shell coiling) of the reno-pericardial system (loss of right auricle and renal organ), reduction of ctenidia (loss of the right gill), and associated circulatory and nervous system changes. There is also a reduction of diversity of shell microstructures, simplification of the buccal cartilages and muscles, reduced coiling of hindgut, and simplification of the stomach. Other characters show an increase in complexity, such as life history characters (e.g., internal fertilization with penis and spermatophores and associated reproductive organs). This increase in complexity is correlated with the ability to produce egg capsules and the evolution of planktotrophic larvae and direct development. There is also an increase in chromosome number, and greater complexity of sensory structures (e.g., eyes, osphradium). In the pulmonates (land snails) the pallial cavity is modified into a pulmonary cavity or lung, while in the opisthobranchs (sea slugs) there are secondary gills and elaborate neurosecretory structures.

Generally, gastropods have separate sexes. One major exception is the heterobranch clade (pulmonates & opisthobranchs), which is exclusively hermaphroditic. Basal gastropods typically spawn gametes directly into the water column, where they are fertilized and develop. Brooding of developing embryos is widely distributed throughout the gastropods, as are sporadic occurrences of hermaphroditism. These basal groups also have non-feeding larvae. Eggs are relatively small in most taxa, although eggs of taxa with non-feeding larvae tend to be a little larger than those taxa that have feeding larvae. Egg size is reflected in the initial size of the juvenile shell or protoconch: when preserved in fossil taxa, this feature has been useful in distinguishing feeding and non-feeding taxa in the fossil record. The first gastropod larval stage is typically a trochophore that transforms into a veliger and then settles and undergoes metamorphosis to form a juvenile snail.

Figure 10 External morphology and diversity of the Gastropoda. Top, typical benthic gastropod mollusc. Bottom, a pelagic heteropod. Modified from Gray, Maria; Figures of molluscous animals, selected from various authors. 1857–1859. Reprinted with permission from Gray, Maria.

Cephalopoda

Cephalopods (Figure 11) are dorsoventrally elongated marine molluscs that may or may not have a recognizable external or internal shell. Cephalopods are the most complex and motile

of the nonvertebrate metazoans and show numerous modifications of the general molluscan body plan. The nautiloids first appear in the late Cambrian and undergo a rapid diversification in the Ordovician. Ammonites (Coleoidea) appear later in the Devonian. Cephalopods are much more variable in their diversity through time than other molluscan groups. They are hit by numerous extinctions (e.g., terminal Permian, Triassic, and Cretaceous events) but typically showed rapid replacement by the survivors. The cephalopods include the largest living as well as the largest extinct molluscs: ammonite shells range to over 2 m across and body sizes of living squid range up to 8 m, with tentacles exceeding 20 m in length. Over 10,000 species are known with about 700 living taxa. All are active carnivores in marine benthic and pelagic habitats from nearshore to abyssal depths.

Cephalopods are thought to have evolved from monoplacophoran-like ancestors. Septa formed at the apex as the animal grew and withdrew into a newly formed body chamber. The old chambers are gas-filled and provide buoyancy for the organism. The foot was modified into a funnel and provides jet propulsion for movement. Prehensile arms with suckers surround the mouth on the head (cephalic in origin) and capture prey. In cephalopods with external shells (ammonites and nautiloids), the shells are composed of an inner nacreous layer and an outer prismatic layer. In other cephalopod taxa the shell is typically internal and reduced to a linear stiffener as in cuttlefish and squid or virtually nonexistent as in the octopus, whose pelagic ancestors reinvaded the benthic realm.

Much of the external anatomy of cephalopods appears associated with their highly motile, pelagic habits. These modifications are so strong that it is difficult to readily identify the typically molluscan body axes in a cephalopod. For example, as a squid jets through the water, the most posterior portion of the body, relative to the direction of movement, is the squid's head with its prehensile arms. The most anterior portion is the dorsal surface of the muscular mantle and the posterior mantle cavity is located ventrally. In addition to jets of water expelled through the funnel, squid and some octopus

use undulating movements of paired fins at the distal end of the mantle for swimming as well.

The cephalopod mouth contains strong beak-like jaws that are used to deliver a lethal bite to prey items as well as shred them; a radula is also present. Salivary glands can produce highly toxic venoms in some squids and octopi, and ink sacs are present in most taxa except *Nautilus*. The digestive system differs from that of most other molluscs in having a cecum in juxtaposition with the stomach and a relatively short intestinal tract. There are two pairs of ctenidia in living *Nautilus*, but all remaining cephalopods (cuttlefish, squid, and octopus) have a single pair of ctenidia. The circulation system also differs markedly from that of other mollusks in being a closed system capable of maintaining a high blood pressure, rather than open and diffuse as in other taxa. The heart consists of two auricles and a single ventricle that supplies multiple arteries. In all cephalopods except *Nautilus*, a pair of branchial hearts situated at the base of the ctenidia pump blood through the ctenidia. The nervous system is highly concentrated and developed in cephalopods. The three major ganglia are fused and organized into lobes, each with its own specific function. *Nautilus* has fewer lobes than other cephalopods, and lobe size may vary among groups with different lifestyles. Coleoid cephalopods also have two large stellate ganglia on the mantle that control both respiratory and locomotory functions of the mantle. Sensory structures include statocysts, olfactory organs, and eyes. Coleoid eyes are surprisingly convergent with vertebrate systems and are capable of resolving brightness, shape, size, and orientation. Cephalopods are also able to change color patterns using an elaborate chromatophore system that is under nervous control; it provides them with the ability to display incredible camouflaging.

Cephalopods have separate sexes and spermatophores are transferred between males and females by modified tentacles. Eggs are large and yolk-rich, and embryonic development of cephalopods is different from that of all other mollusks. There is no larval form, just direct development into juveniles. Both the eggs and young may be brooded, benthic, or pelagic.

Figure 11 External morphology and diversity of the Cephalopoda. Left, squid; right, octopus. (Octopus redrawn from Beesley, P. L., G. J. B. Ross, and A. Wells, *Mollusca: The Southern Synthesis. Part B. Fauna of Australia*, Vol. 5. Copyright © 1998 by Commonwealth of Australia. Reprinted by permission of Australian Biological Resource Study.)

Ecology

Molluscs occur on a large variety of substrates, including rocky shores, coral reefs, mudflats, and sandy beaches. Gastropods and chitons are characteristic of these hard substrates; bivalves are commonly associated with softer substrates, where they burrow into the sediment. However, these patterns are not inflexible. The largest living bivalve, *Tridacna gigas*, occurs on coral reefs, whereas microscopic gastropods live interstitially between sand grains. On hard substrates gastropods are often grazers that feed either selectively or indiscriminately on algal, diatom, or blue-green films and mats or animal aggregations. On soft substrates bivalves typically are suspension or deposit feeders.

The adoption of different feeding habits appears to have had a profound influence on molluscan evolution. The change from grazing to other forms of food acquisition is one of the major features in the adaptive radiation of the group. Based on our current understanding of relationships, the earliest molluscs were likely carnivores and detritivores that indiscriminately grazed on encrusting animals and detritus. Truly

herbivorous grazers are relatively rare in the molluscs and are limited to the polyplacophorans and gastropod groups, whereas living aplacophorans, monoplacophorans, scaphopods, and cephalopods are carnivorous. Some protobranch bivalves are also carnivorous; most bivalves are either suspension or deposit feeders that indiscriminately take in particles but then elaborately sort them based on size.

Cephalopods are typically active carnivores specialized on mobile prey such as fish, crustaceans, and other cephalopods. Because they are so abundant in pelagic systems, cephalopods are often important food sources for larger fishes, marine mammals, and even seabirds. In the gastropods several groups such as Janthinidae are planktic pelagic carnivores whereas the heteropods (Caengastropoda) and the pteropods (Opisthobranchia), like the cephalopods, are active swimmers in search of prey. These taxa spend their entire lives in the water column where they primarily feed on Cnidaria, other molluscs (including small cephalopods), and even fishes.

Bivalve-like suspension feeding has evolved in some gastropods such as the vetigastropod *Umbonium* and in the pelagic gastropod group Thecosomata. Some groups with carnivorous diets have undergone what appear to be true, explosive, adaptive radiations (e.g., the Neogastropoda). Other carnivorous taxa such as the aplacophorans and scaphopods have low diversity and abundance.

In addition to these more typical trophic strategies and interactions, some molluscs (especially among the gastropods) have also become both endo- and ectoparasitic in and on other invertebrates—most often echinoderms. Galeommatoid bivalves and eulimid gastropods occur as ectoparasites on holothuroid and asteroid echinoderms, respectively. The reduced, worm-like Entoconchidae occur in the internal body cavity of holothuroids, whereas the larvae of freshwater unionid bivalves parasitize fish and amphibians, although the adults are free-living.

Molluscan groups are ubiquitous and diverse in marine habitats, but only the bivalves and gastropods have invaded freshwater habitats, and only gastropods have invaded terrestrial ones. The major terrestrial clade is the pulmonates, which originated at least by the Carboniferous, but other nonmarine groups such as the Neritopsina (marine, freshwater, and terrestrial) are likely Devonian in origin. Often the terrestrial groups are among the most basal of the extant taxa in the clade. For example, in the Neritopsina terrestrial taxa are thought to be more basal than marine members of the group. These patterns could result from competition among sister taxa and the relegation of one taxon to a unique habitat while the other diversified in the ancestral setting.

Shell morphology is often thought to be correlated with lifestyle and habitat and some substantial changes in body form are clearly associated with major adaptive changes. However, in many cases gross differences in morphology within a group are not readily correlated with habitat. Conversely, similar shell morphologies do not necessarily indicate similar habits or habitats, making paleocological studies with molluscs problematic. For example, limpets occur on wave-swept platforms, on various substrates in the deep sea, in fast-flowing rivers, or in quiet lakes and ponds. It is often suggested that strong wave action selects for limpet morphologies in several groups, but it is obvious from their

current distributions that limpets do very well in a wide range of habitats.

Molluscs and Humans

Molluscs and humans are most often associated economically. Molluscs have many important commercial benefits such as fisheries and mariculture but can also be responsible for tremendous economic loss and human suffering. Molluscs are found in some of the earliest human habitation sites in southern Africa over 100,000 years ago, and it is likely that humans have included molluscs in their diet and as material resources for millions of years. More recently, commercial fisheries have focused on bivalve, gastropod, and cephalopod taxa for food (oysters, abalone, scallops, clams, cephalopods, and mussels) as well as pearl and button fisheries.

In freshwater habitats molluscs may serve as intermediate hosts for parasites such as digenetic trematodes and are an integral part of the Schistosomiasis contagion that infects millions in the tropical regions of the world. Nonhuman, molluscan-borne parasites are also responsible for more than \$2 billion worth of losses worldwide to the livestock industry each year. Most people are familiar with “garden snails” and the damage they can do to favorite plants, but this local damage is minimal compared to the role of molluscs as pests. Molluscan pest species cause millions of dollars worth of damage to horticultural and food crops throughout the world every year, and as the global economy expands, the probability of potentially damaging introductions increases dramatically. For example, over the past 5 years, almost 5000 molluscs from 100 different countries were intercepted entering the United States.

One of the most notable introductions has been that of the freshwater bivalve *Dreissena polymorpha*, or zebra mussel. Zebra mussels were first detected in Lake St. Clair (Great Lakes chain) in 1988. It is thought that zebra mussels entered the Great Lakes in ballast water of commercial ships from eastern Europe, and without natural enemies to control their numbers, they have thrived and spread to 19 states in less than 10 years. In the United States and Canada, they have caused widespread economic and environmental damage. They typically concentrate where water flows rapidly and therefore can quickly clog intake pipes and cut off water flow to hydroelectric and nuclear power plants, industrial facilities, and public water supplies. One mussel removal project in Lake Michigan removed 400 cubic yards of zebra mussels at a cost of \$1.4 million. Zebra mussels can also have tremendous effects on freshwater ecosystems by displacing native species and increasing levels of toxic algae. As zebra mussels have spread across the country, they have devastated native freshwater clam populations (especially the unionid species) that were already endangered and threatened by pollution and habitat modification.

On a more positive note, molluscs are also important in biomedical and biotechnology research. Although not as well known as model organisms such as the fruit fly *Drosophila*, opisthobranch molluscs are commonly used in neurological studies of learning and memory functions, and bivalve molluscs have served as models for environmental and genetic

interactions in tumor research. Extracts of numerous other molluscs have been examined for antibacterial and other properties potentially useful in the medical and health sciences. Molluscs also provide important model organisms for environmental health studies. For example, bivalve molluscs are frequently used in studies on the toxicology and environmental monitoring of heavy metals and other pollutants.

Molluscan conservation issues are primarily centered on freshwater and terrestrial taxa. The largest number of documented extinctions has involved nonmarine molluscs, and nonmarine molluscs are second to the arthropods in numbers of currently threatened species. Terrestrial species are impacted primarily by the destruction of native vegetation and cover, and freshwater species by alter flow, sedimentation rates, and pollution. Although marine taxa are thought to be less impacted by human activities, populations of some taxa have been substantially reduced by overfishing. These include abalone (*Haliotis*), clams (*Tridacna*), and scallops (*Pecten*). Marine taxa, like freshwater and terrestrial taxa, are also threatened by habitat destruction, pollution, changes in sedimentation patterns, and other factors.

As discussed above regarding zebra mussels, the introduction of exotic species can also seriously impact native taxa. This is especially true on islands where the effective population size may be small. One of the best-documented cases was the apparent extinction of the endemic land snail taxon *Partula* from the island of Moorea in French Polynesia. This resulted because of the intentional introduction of the predatory snail *Euglandina rosea* to the island as a biocontrol agent for the Giant African Snail, *Achatina fulica*.

Classification

Given the state of flux in molluscan and metazoan phylogeny and the wealth of new data that is now appearing from molecular, morphological, and paleontological work, any classification proposed here would be rapidly outdated. Several traditional classifications are available in the references cited in the References. However, few are based on hypotheses of relationships, but are instead based on overall similarity and ad hoc scenarios of evolution.

Classifications based solely on morphology have been especially problematic, and much of this confusion has resulted from problematic taxa such as the aplacophorans, scaphopods, and bivalves where possible reduction and loss of organs or other secondary simplification has produced morphologies that may be argued as either primitive or highly derived. Many classifications have also focused exclusively on the morphology of living taxa and have ignored potential, fossil members of the Mollusca. If extinct fossil taxa are included in evolutionary scenarios, they are typically limited to distinctive clades such as the Rostroconchia and Bellerophononta. Other more problematic extinct taxa (e.g., hyoliths) are systematically ignored, arbitrarily excluded from the Mollusca without analysis, or shoehorned into extant groups.

The sister taxa of Mollusca have included the Platyhelminthes, Annelida, Sipuncula, and the Kamptozoa. Within the Mollusca both Polyplacophora and Aplacophora have

been argued as the most primitive taxon, and thus the out-group to all Conchifera.

Most classifications have assumed a single cladogenetic event in the origin of the Conchifera from the supposedly more primitive placophoran groups. Alternative hypotheses have derived the conchiferans in an unresolved polytomy from a hypothetical ancestral mollusc, or HAM. Some workers have interpreted the Cambrian Burgess Shale taxon *Wiwaxia* and other less complete halkieriid-like fossils as molluscan while others have argued *Wiwaxia* to have annelid worm affinities. However, the discovery of an articulated halkieriid from the lower Cambrian and the existence of these and other multishelled placophorans necessitate the reexamination of long-held assumptions of molluscan ancestry and monophyly. The rapidly increasing knowledge of Coeloscieritophora diversity suggests that they may harbor independent ancestors for extant molluscan groups.

Molecular phylogenies for the Mollusca have not fared much better than the morphological studies. Nuclear and mitochondrial DNA sequences have had very limited success in resolving a monophyletic molluscan clade or even producing robust or reasonable groupings within the Mollusca (e.g., the bivalves and gastropods). These problems most likely result because of the deep, Paleozoic divergence of many of the molluscan taxa and the variable rates of change across molluscan genomes.

The following rank-free classification is conservative and only denotes the major clades within the Mollusca.

- Coeloscieritophora
- Sipuncula
- Hyolitha
- Mollusca
 - Chaetodermomorpha
 - Neomeniomorpha
 - Polyplacophora
 - Conchifera
 - Rostroconchia
 - Bivalvia
 - Protobranchia
 - Pteriomorpha
 - Heterodonta
 - Anomalodesmata
 - Monoplacophora
 - Scaphopoda
 - Dentaliida
 - Gadilida
 - Gastropoda + Cephalopoda
 - Gastropoda
 - Patellogastropoda
 - Vetigastropoda
 - Neritopsina
 - Caenogastropoda
 - Heterobranchia
 - Cephalopoda
 - Nautiloidea
 - Coleoidea
 - Aminonoida
 - Decapoda
 - Octopoda

Glossary

Aposematic Warningly colored; boldly colored, usually involving reds, oranges, or yellows, as well as black and white; less commonly with only black and white pattern elements.

Batesian mimicry Evolutionary phenomenon whereby a palatable species comes to resemble a distasteful, toxic, or otherwise protected species and thereby gains some protection from predators.

Congener A member of a shared genus.

Crochets Hook-like structures at the ends of abdominal prolegs for engaging silk and other substrates.

Detritivore An animal (larva in this article) that feeds on dead organic debris; although the term covers both plant or animal matter, in moths the term is especially apt to apply to leaf litter feeding.

Diapause Period of hormonally controlled inactivity generally associated with weather conditions that are unfavorable to survival or reproduction. Often induced by shortening day lengths in late summer and fall, and broken by warm temperatures in spring.

Hemolymph Translucent yellow to green fluid that fills an insect's body, sharing functions of blood and lymphic systems, but differing in that it does not transport oxygen in most insects.

Hypermetamorphic A life cycle that includes two or more larval forms, with each often specialized for a different feeding function (and larval ecology).

Instar A larval stage; the first instar hatches from the egg and on molting enters the second instar. Most moths

undergo five or six instars prior to pupation; as few as three and more than a dozen occur in various lineages.

Maxillae The second pair of mouthparts, located between the mandibles and the labium; the third pair of mouthparts.

Monophyletic A group with a single evolutionary origin that includes the common ancestor and all of that ancestor's descendants.

Mullerian mimicry Evolutionary phenomenon whereby distasteful, toxic, or otherwise protected species come to resemble one another. In so doing the members of Mullerian mimicry complex gain by more efficiently educating local predators.

Natural group Monophyletic; group with a common origin (i.e., having a shared common ancestor).

Oviposit To lay an egg or ovum.

Parasitoid Predator that lives internally or externally on its host. Parasitoids are parasite-like in that they are smaller than their hosts, feed from within or on the host's body, and often do so over a period of weeks or months, but functionally they are predators because they nearly always kill their host (prey).

Pharate A "cloaked" or hidden stage, for example, the adult moth prior to its emergence from the pupa (which in some noctuid moths can be delayed by more than 7 months).

Pheromone A chemical released by one individual that elicits a response in a second individual of the same species.

Polyphagous Eating plants from more than two unrelated plant families.

Introduction

Every night at dusk one and a half million Mexican free-tailed bats flood out from beneath the Congress Avenue Bridge in Austin, Texas. Bats from this single colony harvest more than 10,000 pounds of insects every evening, most of which are moths. Moth caterpillars account for much of the above-ground insect biomass in temperate forests; without them one wonders whether there would be songbirds to usher in each spring. Estimates of species-richness for moths have climbed steadily over the past decade, with the more modest extrapolations falling between 200,000 and 300,000 species. Whether measured in terms of biomass, influence on terrestrial ecosystems, or species-richness, moths must be held as one of the most successful lineages of macroscopic organisms on this planet.

Body sizes span two orders of magnitude: nepticulid and heliozelid leaf miners, some with wingspans under 3 mm, are little more than aerial plankton (Figure 1). The world's largest moth, a neotropical erebid, has a wingspan that sometimes

exceeds 275 mm. All members of the order Lepidoptera can be diagnosed by the presence of scales, which cover the wings and body. A second readily observable structure that is part of the order's ground plan is the epiphysis, a cuticular flap on the inside of the foreleg, which is used by many moths to clean the antenna. A curious lepidopteran attribute is the production of apyrene (anucleate) sperm – in some species 80% or more of the sperm is apyrene and therefore incapable of fertilization. Kristensen (1984) identified nearly two dozen other uniquely derived structures, which, taken as a whole, incontrovertibly established the monophyly of the Lepidoptera and its sister-group relationship with the Trichoptera (caddisflies). Recent molecular studies have corroborated the major findings of Kristensen.

Butterflies and moths make up the order Lepidoptera. Because butterflies derive from within one (or two) moth lineages, it is not possible to identify uniquely evolved features shared by butterflies that are not also found in some moths. Recent phylogenetic reconstructions indicate that butterflies have their closest relatives with the Hedyliidae, an odd-looking

Figure 1 *Stigmella aceris* (Nepticulidae); adults have a wingspan of only 4 mm. Note most of the wing surface area is made up of cilia-like scales. Courtesy Erik Nieuwerkerken.

Figure 2 *Macrosoma nigramacula* (Hedylidae); both morphological and molecular place these moths as a subgrouping within the butterflies (Papilionoidea and Hesperioidea). Courtesy Arthur Anker (UFC, Brazil).

group of neotropical moths that were formerly classified in the Geometroidea (Figure 2). Three independent molecular studies place hedyliids within the butterflies – stated differently, some butterflies are more closely related to hedylid moths than they are to other butterflies. But regardless of the phylogenetic position within the order, since butterflies are, evolutionarily speaking, nothing more than diurnal moths (and negligible in terms of species richness), “Lepidoptera” and “moths” are used synonymously throughout this article.

Higher Classification

Phylogenetic relationships among the early lineages of Lepidoptera are among the best known of any insect order, so well that they have even been used as a “truth table” for testing the phylogenetic signal in several gene sequencing studies. The

basal branches on which the order’s extraordinary evolutionary successes have been built are shown in Figure 3.

The Four Suborders: The Base of the Tree

Recent higher classifications for the Lepidoptera recognizes four lepidopteran suborders: Zeugloptera, Aglossata, Heterobathmiina, and Glossata (Kristensen, 1998, and authors therein; van Nieuwerkerken *et al.*, 2011; Figure 3 and Table 1). The first and most basal lineage within the order contains a single family, the Micropterigidae, with approximately 250 known species (some 90 of which are still undescribed) distributed across the major continents. Decidedly primitive, this family shares numerous morphological traits with the Trichoptera (caddisflies). Noteworthy are the functional mandibles in the adult (homologous with those of other chewing insects) that are used to grind up pollen and fern spores. The larvae – largely bryophyte feeders – are bizarre creatures with little morphological affinity to other lepidopterans (Figure 4(a)); so odd are the caterpillars that at one time these moths were placed in their own order. The spore and bryophyte feeding by adults and larvae, respectively, reflect the family’s archaic origins. The Aglossata contains a single *Araucaria*-feeding family the Agathiphagidae with two species, restricted to Australia, New Caledonia, and a few Pacific islands. The third suborder, the Heterobathmiina, is represented by about nine species from temperate areas of Chile and Argentina. So far as is known, all heterobathmiids feed on *Nothofagus* (southern beech), an ancient group of woody angiosperms. Hence, all three of these early lineages have life histories that may agree in detail with those of their earliest Mesozoic ancestors. The remaining diversity occurs in the Suborder Glossata, which possess, among other traits, a coiled proboscis that can be used to siphon up nectar and other liquid substrates. The Glossata includes approximately 41 superfamilies, all but two of which (Hesperioidea and Papilionoidea) are moths.

The Glossatans

Four major clades are recognized within the Glossata: Dacnonypha, Coelolepida, Myoglossata (Neopseusida), and Neolepidoptera. The most basal lineage within this assemblage is the Dacnonypha, with one family, the Eriocraniidae. Eriocraniids are small handsome moths with metallic gold and purple scales known only from the Northern Hemisphere. The two dozen recognized species are leaf miners in new leaves of Fagaceae, Betulaceae, and Rosaceae. Coelolepida include the Acanthopteroctetidae and Australia’s lophocoronids. The biology of the Acanthopteroctetidae is poorly known – one is a miner in *Ceanothus* (Rhamnaceae). Likewise, the life history of all six lophocoronids remains unknown: the piercing ovipositor is suggestive that the female lays the eggs within tissues and that the larvae are internal feeders. Neopseustids are peculiar insects that superficially resemble lacewings and other neuropterans. Larval stages are unknown, but again the shape of the female’s ovipositor is suggestive that larvae feed internally; the 14 species are found in southern South America, China, and Southeast Asia. The last clade, the

Figure 3 Phylogenetic tree for major lineages of moths. Adapted from Kristensen NP (ed.) (1998) *Lepidoptera, moths and butterflies, Vol. 1. Evolution, systematics, and biogeography Part 35 Arthropoda: Insecta. Vol. IV. In: Zhang Z-Q (ed.) *Animal biodiversity: An outline of higher-level classification and survey of taxonomic richness. Zootaxa* 3148: 212–221.

Neolepidoptera, includes the remainder (>99.8%) of the ordinal species diversity.

The Neolepidopterans

Two infraorders are included: Exoporia and Heteroneura. Exoporia, with six families and more than 636 species, are the only basal moth lineage with appreciable extant diversity. Three of the families are Gondwanan: Mnesarchaeidae (New Zealand, 14 species; seven described), Prototheoridae (South Africa, 12 species), and Anomosetidae (Australia, one species). The largest family, the Hepialidae, with approximately 629 species, is cosmopolitan; although the vast majority of the generic diversity is Gondwanan. The remaining 34 superfamilies are placed into the Heteroneura – the name referring to the venational differences between the fore- and hindwings. Evolutionary relationships among the heteroneuran lineages remain equivocal even in the face of detailed morphological and molecular studies. *van Nieuwerkerken et al.* (2011) recognized two basal (super)clades: the Nepticulina (two included families) and Eulepidoptera (for all remaining Lepidopteran diversity). The latter, in turn, includes four principal clades: Andesianoidea (one family); Adeloidae (five included families); Etimonorysia for Paleaphatoidea and Tischerioidea, each with one family; and Ditrysia. Much of the phylogenetic uncertainty about heteroneuran relationships is believed to be a consequence of rapid diversification within the suborder, with

evolutionary events occurring so closely together in time that it has been difficult to accurately reconstruct their sequence. As a group, heteroneurans tend to be internal feeders: most are leaf miners but some also tunnel in stems, buds, and seeds. Among the adeloids are the yucca moths, highly specialized yucca-pollinating mutualists that have been the focus of numerous coevolutionary studies. The most diverse lineage is the (leaf mining) Nepticulidae, with more than 800 named species and perhaps again as many awaiting description. Collectively, all of the aforementioned relictual taxa comprise only about 1.2% described species diversity of Lepidoptera, a percentage that will continue to shrink appreciably as more tropical moth species are described. Ecologically and taxonomically moth diversity is about ditrysians.

The Ditrysia

The remaining 29 heteroneuran superfamilies are placed in the Ditrysia, a group whose monophyly is well supported by the presence of separate copulatory and ovipositional pores, an internal duct that connects the two, and the unique organization of the proboscis musculature. Published phylogenies for ditrysiian superfamilies and families are replete with uncertainty. Considerable genetic data will have to be collected before consensus is reached about evolutionary relationships of the families and superfamilies within this remarkably successful group of insects.

Notodontidae		3800
Totals	124	157,402

Diversity figures were taken from the latter and exclude 86 named fossil taxa. Species-numbers are given for all 44 superfamilies. Families, other than the nominate, that contain more than 2000 described species are given. A few additional families and subfamilies that are mentioned in the text or otherwise deemed to be of special importance are also included. Note: The phyletic sequencing, taxon order, and many of the ranks used here are approximations of evolutionary relationships, for example, the Subclade Macroheterocera is subordinate within the Obectomera, which in turn is subordinate within the Apodytrisia – taxon (clade) names are best used without their ranks.

Many guides and faunal works divide the Lepidoptera into the so-called Microlepidoptera and Macrolepidoptera. Microlepidoptera roughly corresponds to the basal groups, most of which are small to minute, possess a fused CuP vein in the hindwing, have the larval crochets arranged in a circle, and possess a jugum or the remnants of one (all of which are primitive features that were part of the ground plan for the order). It is a grouping of convenience as the “macros” are clearly derived from the “micros,” and therefore some micros are more closely related to the macros than they are to other micros. The Macrolepidoptera, once thought to be a monophyletic grouping that included the butterflies and the last five superfamilies in [Table 1](#) (most larger moths), has been shown to be a polyphyletic entity – pyraloids would need to be included if the term were intended to reflect a natural group.

Fossil History

Whereas the fossil record of the Trichoptera, the sister group to the Lepidoptera, is adequate and dates into the Permian, the record for lepidopterans is meager, especially for Mesozoic-aged fossils, when the basal lineages were diversifying. There are less than a dozen putative lepidopteran fossils from the Triassic, and most of these cannot be assigned to the order with certainty. The oldest unequivocal moth, *Archeolepis mane*, dates to the Lower Jurassic. By definition, sister taxa are of equal age, and thus it is curious that the oldest caddisfly and moth fossils are of such disparate ages. Skalski has suggested the possibility that some early stem group lepidopteran fossils may be unrecognized because they have been erroneously assigned to the Trichoptera.

More than a dozen moth fossils from the Upper Jurassic and Cretaceous are unassignable to a family. Although most of these clearly belong to preglossatan taxa, this is not true of all. *Protolepis cuprealata* from Upper Jurassic deposits in Kazakhstan appears to have a coiled proboscis, although an alternative interpretation is that the structure in question be an elongate maxillary palpus.

Micropterigids have been identified from several amber and sedimentary deposits. Examples from the lower Cretaceous represent extinct genera, whereas those from the Tertiary are assigned to modern genera. There are no fossil records for either the Aglossata or Heterobathmiina. Glossatans, including a putative lophocoronid, are well substantiated from the Upper Cretaceous. By 102 mya, modern genera of ditrysians are recognizable, suggesting that early evolution of the order occurred on nonseed plants and gymnosperms during the late Jurassic ([Labandeira et al., 1994](#)). Not surprisingly, most of the modern

superfamilial and species diversity appears after the angiosperms began radiating in the early Cretaceous. The oldest unambiguous macrolepidopteran fossils are Paleocene.

Leaf mining families from the Northern Hemisphere have an extensive fossil record that is believed to reflect their ages of origin as well as their relative abundances. The discoveries of [Labandeira et al. \(1994\)](#) of *Ectoedemia*-like and *Stigmella*-like mines (both Nepticulidae) and a phyllocnistine (*Gracillariidae*) from Albian deposits (102 mya), which agree in detail with those of modern species from related host taxa, are noteworthy in that they demonstrate the antiquity of many moth–plant associations. Another well-represented group of fossil moths are the tineoids, which are richly represented in Dominican amber deposits that date from 40 to 15 mya.

Species Diversity and Biogeography

There is still considerable doubt about the species richness within the order, an alarming observation given that Lepidoptera are among the most well-studied groups of invertebrates. The recent compilation by [van Nieukerken et al. \(2011\)](#) lists 157,402 species. [Heppner's \(1998\)](#) earlier figures for global diversity by biogeographic region are shown in [Table 2](#). He guessed that half again as many species remain to be described, and that richness for the order would climb to 255,000 species ([Table 2](#)). [Gaston \(1991\)](#) and [Kristensen \(2007\)](#) have offered higher estimates, in the range of 300,000–500,000 species.

Heppner's tallies indicate that 92% of Palearctic Lepidoptera have received names ([Table 2](#)). The richest biogeographic realm, the Neotropics, with an estimated 35% of the world's butterfly and moth fauna, has only about 50% of its fauna named. Moreover these figures may be conservative. In recent revisions of neotropical tineids and tortricids 75–90% of the species were regarded to be new. Of the more than 250 species of *Gracillariidae* that were collected at the La Selva Biological Station in Costa Rica, 98% were believed to be undescribed.

There can be little doubt that microlepidopterans will be a frontier for descriptive taxonomy for decades if not centuries. In general, small cryptically colored taxa have greater proportions of unnamed species. Also, species-rich taxa that are intractable taxonomically have proportionately greater numbers of undescribed species. Microlepidopteran superfamilies with especially high numbers of unnamed species include the Tineoidea, *Gracillarioidea*, *Gelechioidea*, and *Pyraloidea*. But even among the Macrolepidoptera, considerable taxonomic work remains, especially for neotropical taxa. The only two appreciably diverse moth families where the descriptive

taxonomy is approaching completion are the Saturniidae and Sphingidae, veritable behemoths among insects that have long held favor among collectors.

Present tallies suggest that the Noctuoidea is without parallel in richness, with 42,407 described species, most of these falling within the Erebidae and Noctuidae (Table 1). It is the most species-rich superfamily on all continents except Australia, where its preeminence is superseded by the Gelechioidea. Moreover, many thousands of noctuoids await description, particularly in the Neotropics. Current tallies of described species place the Geometroidea second in richness with some 23,748 species worldwide, nearly all of which are in the nominate family. Its present ranking could fall to fourth once world microlepidopteran faunas are studied. Presently, there are approximately 18,489 described species of Gelechioidea and 15,576 Pyraloidea, either of which could contain more than 50,000 species and prove to be the most species-rich superfamily within the Lepidoptera. The butterflies, with 18,768 species, will rank no higher than fifth in global importance. In the most well-studied faunas (i.e., those of the north temperate zone and Australia), moths generally comprise about 95% of the lepidopteran species diversity, with butterflies making up the remainder. In terms of biomass and number of individuals, moths and their caterpillars probably have even greater (ecological) importance.

Because tropical faunas are incompletely known, especially for microlepidopterans and smaller Geometroidea and Noctuoidea, a quantitative assessment of global diversity patterns for the entire order is not yet possible. Nevertheless, virtually all lepidopterists are in agreement that greatest species, generic, familial, and superfamilial diversity is found in tropical rain forests. Preliminary estimates of the moth fauna of Costa Rica (51,100 km²) run between 13,000 and 16,000 species and thus are roughly comparable to the species diversity of the entire North American continent north of Mexico or that of Australia, areas 380 and 150 times greater in size, respectively. Taxa with exceptional tropical richness include the Erebidae, Gelechiidae, Geometridae (especially in middle and higher elevations), Oecophoridae, Notodontidae, and Pyraloidea.

Given that moths are quintessentially phytophagous, their species diversity should parallel that of vascular plants. If this is correct, the highest global richness should occur on the low- to mid-elevational slopes around the Amazon basin. The forests of Southeast Asia and Indo-Australia also would be expected to harbor hyperdiverse moth faunas. In temperate regions, the floras of South Africa and southwestern Australia are among the richest in the world. These latter areas are noteworthy because they support comparatively high percentages of nonditrysian moths and hence can be regarded as two of the world's most important "living museums." Not all moth taxa are hyperdiverse in the tropics. Familial, generic, and species diversity for the nonditrysian moth lineages is highest in extratropical latitudes. In temperate areas of the Northern Hemisphere, the Coleophoridae are numerically important Lepidoptera in grassland, scrub, and desert ecosystems, yet the family appears to be absent in the rain forests of Central America. The Tortricoidea also appear to be less diverse than would be predicted based on the latitudinal richness gradients seen in other Lepidoptera.

On a local scale, Lawton has shown a correlation between herbivore richness and host plant architecture. Trees have more architectural complexity and therefore more herbivores than shrubs, shrubs more than herbs, and so on. An example of the importance of trees is provided by white oak (*Quercus alba*) – across its range in eastern North America it hosts more than 400 species of moths (this number includes both specialist and generalist feeders). It follows that ecosystems with high tree diversity (e.g., lowland tropical rainforests) would have especially rich moth faunas.

Island faunas, especially those of distant islands, are always unbalanced with respect to those of the nearest continents. Macroheterocerans that tend to be well represented on islands include the Erebidae, Geometridae, Noctuidae (especially Heliothinae and Noctuinae), and Sphingidae. Despite their small size, microlepidopterans are present even on remote islands, presumably because they disperse effectively as aerial plankton. Hawaii has been colonized by dozens of different microlepidopteran lineages that can be characterized as weak fliers. A second example: the richness of all leaf mining families (minute to small moths) on Santa Cruz Island, off the coast of California, is nearly that of the mainland, whereas most groups of larger moths and other insects are represented by less than half of the mainland fauna.

Life History

Egg

The ova are variable in shape and surface ornamentation. Microlepidopterans often have flat, smooth eggs, many of which are nearly transparent once laid on a leaf surface; those of macrolepidopterans tend to be raised. The latter may be round, square, disk shaped, or spindle shaped; the chorion (outer surface) varies from smooth to richly ornate. Females generally deposit the egg within or on the surface of the host; in the latter case, secretions released from the accessory glands bond the egg to the substrate. Females of some taxa leave behind abdominal scales, which discourage natural enemies or advertise to other females that the resource already has been found. A few polyphagous species (e.g., arctiines and hepialids) broadcast the eggs as they fly. The latter family also includes the world's most fecund lepidopteran – a single female *Abantiades hyalinatus* laid 30,000 eggs (and died with another 20,000 ova remaining in her abdomen).

Larva

The larva (Figures 4–9) is the principal feeding stage, increasing its mass by four (to five) orders of magnitude during its development. There are from three to more than a dozen larval instars, with five being the mode. Dyar was the first to note that there is commonly a linear increase of 1.3–1.4 in head dimensions between successive instars. Dyar's rule holds across many lepidopteran families and often is employed to infer the number of larval instars. In bombycoids and a few other groups the females may pass through an additional instar. Development is remarkably fast in some species, especially those that feed on ephemeral tissues such as fruits and

Figure 5 Moth caterpillar defense (also see **Figures 6–9**). *Isa textula* (Limacodidae). *Isa* caterpillars are armed with hundreds of stinging setae. The setae, positioned about the caterpillar's periphery, may be especially efficient at repelling ants.

Figure 6 *Phobetron pithecium* (Limacodidae). *Phobetron* caterpillars are thought to mimic the cast “skins” of tarantulas, which contain thousands of deciduous urticating hairs – *Phobetron* caterpillars do not sting and are thought to be harmless. Courtesy Noble Proctor.

new leaves and across many desert dwellers. Larger moths of high latitudes may take 2 or 3 years to mature. In *Gynaephora groenlandica* – a lymantriine erebid found well north of the Arctic Circle – caterpillars mature over a 14-year period.

Hypermetamorphosis – where two or more larval forms occur, each specialized for different functions – is rare within the order. The best-known example occurs in the minute to small leaf-mining moths of the family Gracillariidae. In most genera the first two or three instars are flat, legless, possess anteriorly directed mouthparts, lack a spinneret (silk-spinning organ) (**Figure 4(b)**), and feed in a single cell layer, usually the epidermis. The diet is liquid, the larva filtering plant fluids from damaged cells. In later instars the larva takes on a rounded form that is legged, possesses a spinneret, and the mouthparts are directed ventrally (as in other externally feeding caterpillars) (**Figure 4(c)**), and consumes whole cells

Figure 7 *Automeris postalbida* (Saturniidae). *Automeris* caterpillars are fortified with a battery of urticating setae – the effect of which is not unlike that of stinging nettle.

Figure 8 *Euproctis chrysorrhoea* (Lymantriinae, Erebidae). *Euproctis* caterpillars have red middorsal glands on the sixth and seventh abdominal segments that yield a *pot pourri* of defensive secretions – this species purportedly was responsible for two human deaths in Massachusetts.

and tissues. The spinneret is critical in that it is employed by the larva to lay down silk within the mine drawing it into a bubble, thereby creating a space where a rounded body and legs are appropriate. Metamorphosis in some opostegids, *Bucculatrix*, epipyropids, cyclotornids, and others is also hypermetamorphic. Nonfeeding instars are rare, generally occurring in the first or last instars. An example of the former is provided by some zygaenoids. In a number of gracillariids (e.g., *Cameraria* and *Marmara*) there may be as many as two nonfeeding prepupal instars. Whereas a general loss of color is common among prepupae, some turn pink to scarlet prior to pupation (e.g., some Prodoxidae, Gracillariidae, Elachistidae, and Notodontidae).

Pupa

In the most basal lineages the wings, legs, and antennae are weakly fused to the main body of the pupa (**Figure 10**). In some of these, the pupal mandibles, which may be impressively large (**Figure 10(a)**), are used to cut through the cocoon or work the pharate adult free from the pupal

Figure 9 *Hemeroplanes* sp. (Sphingidae). Courtesy of Phil De Vries. *Hemeroplanes* caterpillars are superb snake mimics, despite the fact that mature larvae are but several centimeters in total length. Courtesy of Phil De Vries.

crypt. In heteroneurans the appendages are fused to the body and the mandibles are much reduced and immobile (**Figure 10(c)**). Another phylogenetic trend involves the degree of fusion between adjacent abdominal segments. In the most archaic moths the first seven abdominal segments are movable. Intermediate degrees of fusion occur among microlepidopterans. In the Obtectomera, a clade that includes 12 of the most derived lepidopteran superfamilies (**Figure 3**), the first four abdominal segments are fused and are immobile with respect to one another. Taxa with appreciable abdominal mobility often extrude the anterior end of the pupa from the cocoon or pupal crypt prior to emergence (e.g., most microlepidopterans). Those with a high degree of fusion hatch within the cocoon or pupal crypt and must crawl free before expanding their wings (e.g., all Obtectomera). Male pupae have a single set of paired genital marks on the venter of the ninth abdominal segment; females have an additional paired set of genital “scars” on the eighth segment as well (e.g., **Figure 10(b)**). The pupal stage may be as short as 67 days or may last several years, the latter is not unusual among species that inhabit arid environments.

Most moths spin a cocoon on or within the larval substrate or find their way to the ground and pupate in litter or duff.

The cocoon may be a highly elaborate affair that takes days to spin. The most famous example is that of the Oriental Silk moth (*Bombyx mori*); the cocoon is fashioned from a single strand of silk that, when unwound, stretches for more than half a mile (0.8 km). A curiously elaborate cocoon is made by *Marmara* and related genera in the Gracillariidae: the cocoon is ornamented with sometimes more than 100 anally extruded bubbles, each of which is nearly the diameter of the caterpillar’s body. Cocoons represent a significant energetic investment, in that silk is entirely protein, and the nitrogen that goes into its production is generally in short supply in plants. In addition to silk, the cocoon may incorporate excrement, scrapings from the larval substrate, or larval setae (especially if these are stiff, poisonous, or urticating). Prepupal limacodids discharge a calcium oxalate solution over the inner surface of the cocoon that hardens the cocoon as it dries. Open, netlike cocoons are often spun by species with aposematic pupae. Taxa that pupate in concealed sites such as below ground or in wood often forego spinning a cocoon. A few moths (e.g., elachistines, pterophorids, sterrhine geometrids, and hedylids) pupate naked, exposed on surfaces, like butterflies.

Diapause and Quiescence

Diapause may occur in any of the four life stages. The largest fraction of temperate moths pass through the winter months in diapause as prepupal larvae or pupae; the second largest fraction overwinters as eggs. Moths that overwinter as adults invariably need to feed over 5–7 months of winter – some of these are among the unwelcome guests in the buckets used to collect maple syrup. Reproductive diapause is the rule among moths that overwinter as adults, with ovarian maturation and mating being delayed until the arrival of spring. Summer diapause and estivation occur in many groups that live in habitats with a pronounced dry season. Enormous aggregations involving tens of thousands of moths (usually noctuids) are known to assemble in caves or on (hill) mountain tops. Moths in these aggregations become important sources of protein for vertebrates, even for grizzly bears. The diapause longevity record belongs to the desert-inhabiting prodoxids – single larval cohorts may yield adults over a period of three decades.

Feeding Biology

Larvae

Given the enormity of the order it is remarkable how little diversity there is in feeding habits. More than 99% of all moths are fundamentally herbivorous. Within this realm, however, they have radiated to exploit virtually every corner of niche space. Terrestrial algae, lichens, fungi, bryophytes, pteridophytes, and seed plants are eaten. All plant tissues and organs are consumed, but especially leaves, meristems, and reproductive structures. A majority require living tissues, sometimes of a very specific age, whereas others subsist on dead and fallen leaves and wood.

The most basal moth lineage (Micropterigidae) with larvae reliant on nonseed plants account for about 1% of extant

Figure 10 Moth pupae: (a) *Agathiphaga* sp. (Agathiphagidae). (b) *Sthenopis auratus* (Hepialidae). (c) *Asota* (Erebidae). Across this phylogenetic progression there is reduction in the mandibles, increased fusion of appendages, simplification in the external expression of the appendages, and decreased abdominal mobility. (a) and (c) Reproduced with permission from Kristensen NP (ed.) (1998) *Lepidoptera, moths and butterflies. Vol. 1. Evolution, systematics, and biogeography Part 35 Arthropoda: Insecta. Vol. IV. Handbook of Zoology*. Berlin: Walter de Gruyter, and (b) reprinted with permission from *Journal of the New York Entomological Society* 97, 7.

species diversity. The order's great species, generic, and even familial radiations were reliant on the diversification of the angiosperms. The first radiation of note, as measured by extant richness, was that of the Hepialidae, with some 620 species worldwide. Their success may be due to their diet, which is arguably the most diverse of any moth family. Larvae eat bryophytes, pteridophytes, and seed plants (including both conifers and hardwoods); leaf and especially woody root and stem tissues; leaf litter and fungi, especially in early instars. Many are cannibalistic, and some even attack and consume soft-bodied arthropods. Another early lineage with remarkably catholic diets are the tineoid families, a high percentage of which are fungivores and detritivores. Members of the Tineidae (e.g., the clothes moths) are noteworthy for their ability to metabolize keratin, the normally undigestible protein that makes up fur and feathers. Others feed in bird and bat guano, dung, and even the dead insects that accumulate below spider webs.

As the Lepidoptera radiated so did their feeding habits and their associations with plants (Powell *et al.*, 1998; Menken *et al.*, 2010). A majority of microlepidopterans are concealed feeders, tunneling into plant tissues, forming leaf mines or shelters, or feeding from within silken cases. Galls are made by some members of more than a dozen families, but none of the lineages can be regarded as particularly successful. Diets tend to be specialized in internal feeders because the host is not only the food but also the environment for some or all of the immature stages. The most intimate host associations occur in taxa where the adults and larvae utilize the same host plant, the most famous example being that of the yucca moths in the

genera *Tegeticula* and *Parategeticula* (Prodoxidae). The female yucca moth uses special maxillary "tentacles" to collect yucca pollen and then flies to a second flower where she scrapes the pollen over the stigmatic surface. She then deposits one to a few eggs in the developing ovary, and in so doing, leaves a chemical signature that can be detected by other females. The larvae are seed predators but do not consume all the seeds in a fruit. The mutualism is obligate, as neither moth nor yucca can survive without the other. Two additional moth-pollination mutualisms have come to light over the past two decades. Senita cactus is pollinated principally by a crambid in the Sonoran Desert, and gracillariids in the genus *Epicephala* pollinate members of the Phyllanthaceae genus *Glochidion* in Southeast Asia. As in yucca moths, after actively pollinating a flower the females oviposit in the flowers and the larvae mature on developing seeds.

Leaf miners, minute moths whose larvae feed between the two surfaces of a leaf, account for some early radiations (Menken *et al.*, 2010). The Nepticulidae, whose fossil history traces back more than 102 million years to the Albian, contains more than 1000 species with at least this number remaining to be described. Gracillariidae, with 2200 recognized species and perhaps three times as many unrecognized, also trace their fossil history back to the Albian. The latter family contains members that have been the first shelter-forming Lepidoptera. Early instar gracillariines mine in leaves as do other gracillariids, but middle instars may exit the mine to form a leaf shelter in which they complete their development.

The three largest microlepidopterans superfamilies (the Gelechioidea, Tortricoidea, and Pyraloidea) are concealed

feeders, mostly leaf rollers or shelter formers, but others are borers, leaf miners, gall formers, and detritivores. A handful are predators, inquilines in galls or nests of social insects, and so on. Leaf rollers and shelter formers exhibit intermediate levels of host plant specialization, but polyphagy is not common. An important exception are many tortricids, especially among members of the nominate subfamily that are generalists on woody plants. Several microlepidopteran families have representatives that are external feeders for one or more instars (e.g., the Bucculatricidae, Schreckensteiniidae, Pterophoridae, and others), but none accounts for appreciable present-day diversity. The most species-rich lineage of externally feeding microlepidopterans are the zygaenoids, which as a group appear to be well protected – their arsenal includes urticating spines; abundant, long, or dense setae and hairs; and cyanoglucosides (Figures 5 and 6).

Roughly 55% of the described Lepidoptera are external feeders. Polyphagy is common among external feeders and is the mode for many macroheteroceran families (e.g., Lasiocampidae, Saturniidae, ennomine Geometridae, Lymantriinae, and some subfamilies of the Noctuidae). It is worth noting that many species that are host plant generalists across their geographic range specialize on just one or a few plants at any one locality (Fox and Morrow, 1981). Regardless of the mode of feeding, internal or external, caterpillars that feed on poisonous plants tend to be host plant specialists.

Fungivory appears throughout the order but is only common in the Hepialidae and Tineoidea. The line between fungivory and feeding on fallen plant material is often an arbitrary one (see Rawlins, 1984) – both of these groups are also detritivores. Other sizable lepidopteran clades, with members specializing on fallen leaves, decaying wood, and other nonliving plant tissues, include the herminiine (Erebidae), Blastobasidae, Lecithoceridae, Oecophoridae, some Australian Tortricidae, and a few pyraloid lineages. In pineland, hardwood, and especially mixed forests of the eastern USA, herminiine erebids may account for more than half of all macrolepidopterans in light trap collections during the month of July. Australia has an exceptionally rich fauna of litter-feeding Oecophoridae and Tortricidae (Common, 1990). There, numbers are so great in eucalyptus forests that the larvae are believed to play a significant role in litter processing.

The most common type of carnivory in the order is cannibalism, often showing up in taxa where the host substrate is limited (e.g., annual plants and architecturally reduced perennials) or where movement between hosts is either impossible or exposes larvae to considerable risks (e.g., internal borers). Essentially phytophagous species that occasionally eat other caterpillars occur sporadically across the order. The Epipyropidae and Cyclotornidae are obligate ectoparasites of homopterans. The latter is only parasitic in the first instar; the second to final instars are brood predators in ant nests. About 200 lepidopterans are known to be predaceous, many of which are lycaenid butterflies. The most common prey are sessile or nearly sessile insects, such as the brood of ants or aphids, scale insects, and related homopterans. Hawaii has spawned the most exceptional predaceous caterpillars – members of the genus *Eupithecia* (Geometridae) are sit-and-wait predators that snatch small insects that are so unwise as to crawl over the caterpillar's body.

Special cases are legion, and worthy of their own review. Crambid acenotopines, which number more than 700 species, are aquatic as larvae, with some even adapted for life in rapidly flowing water. The caterpillars feed on submerged aquatic plants tissues or algae. No other Lepidoptera families have yielded speciose lineages that are aquatic or even subaquatic. Adults of three chrysaugine pyralid genera are found on or about sloths, awaiting the once-weekly release of dung, which serves as the substrate for the developing larvae. Other chrysaugines have diversified into a strikingly varied set of niches: North American species include predators of paper wasp brood, cattail borers (Monroe, 1972). *Tallula watsoni*, a phycitine pyralid, has a particularly unusual diet, its larvae feed as inquilines in the webs of a subsocial spider (*Anelosimus studiosus*).

Adults

Micropterigids are mandibulate and use their jaws to grind up pollen and fern spores. An archaic proboscis, formed from the maxillae in Dacnonypha (and other Lepidoptera), is used by adults to collect fluids from bark and other surfaces. These fluids may include dissolved honeydew, but adults do not visit flowers for nectar. Nectar feeding with a coiled proboscis is first seen in the Incurvariina and is retained by virtually all the larger lineages of moths that follow. In addition to nectar and other sources of dissolved sugars, moths use the proboscis to imbibe water, liquids from injured plants and tree flows, dissolved salts (including human perspiration and lacrymal secretions), pus, animal excreta, substances from the crushed bodies of other insects, rotting fruit, dung, carrion, and many other substrates. Calpine erebids use their short, stout proboscis to pierce fruits. A few calpines have taken to collecting lachrymal secretions of birds and mammals; in the most extreme cases, an armored proboscis is used to pierce skin and take blood meals from mammals. At least heliconiine nymphalids and perhaps others have the ability to solubilize (e.g., alkaloids) and even digest solid (e.g., pollen) substrates by pumping oral fluids down through the proboscis.

A favorite collecting technique for moths is “sugaring.” A standard bait is made by mixing fruit, beer, and sugar. Whereas overripe bananas are the most universal ingredient, collectors sometimes add watermelon, apricot, grapes, rum, jellies, molasses, and a rather long list of other substances, some of which might best be left unnamed. Once the mixture has been allowed to ferment it is then applied to tree trunks or offered on sponges. Virtually all of the winter-active moths (e.g., Oecophoridae, Tortricidae, and Noctuidae) feed at bait. During summer months, many moths in dry woodlands also come to bait. Presumably, moths that are attracted to bait normally would be feeding at tree wounds, sap flows, rotting fruit, or the honey dew secreted by homopterans.

Plant tissues tend to be low in sodium relative to the metabolic needs of animals. Many lepidopterans reach adulthood with inadequate supplies of this essential element, but they are able to acquire it by imbibing fluids from mud puddles and water courses (Figure 11), urine, sweat, and lacrymal secretions. Although “puddling” is well known among butterflies, it also occurs in a diverse array of diurnal and nocturnal moths. In most moth and butterfly species,

Figure 11 *Urania leilus* (Uraniidae). Sunset moths are among the most dazzling of all invertebrates. Males are puddlers that supplement their metabolic needs with the dissolved sodium found in mud and other sources – see Adults. Courtesy of Tom Murray.

90–100% of the individuals that puddle (or feed at other sodium-rich substrates) are males. A remarkable case is provided by *Gluphisia septentrionis* (Notodontidae). Puddling males will drink (and forcibly excrete) more than 600 times their own body weight in a single evening. *Gluphisia* males transfer sodium to females with their ejaculate; females in turn pass much of the sodium to their offspring.

Many adult moths lack functional mouthparts or digestive systems, including many (or all) Apatelodidae, Arctiinae, Bombycidae, Hepialidae, Lasiocampidae, Lymantriinae, Notodontidae, Saturniidae, and Zygaenoidea. Adults of late fall and early spring geometrids also tend to be nonfeeding, whereas those that fly during the summer commonly consume nectar.

Natural Enemies and Chemical Defense

Natural Enemies

Moths are fecund invertebrates that produce 100–10,000 times more ova than will ultimately survive. A panoply of biotic and abiotic mortality factors comes into play during every life stage (and larval instar) to limit population growth. Biotic factors include an enormous range of pathogens, parasites, and predators. Population numbers of many pest species, especially in forests and other stable communities, often are controlled by viruses, bacteria, and fungi. Viruses are often highly specific, and one wonders if there might be nearly as many lepidopteran viruses as there are moths and butterflies. There are comparatively few recorded species of bacteria and fungi that attack insects, but the taxonomy of insect pathogens, especially those that cannot be easily cultured, is understudied; although some are highly specific, others have broad host ranges. *Bacillus thuringiensis*, the most widely used pathogen for the control of Lepidoptera in gardens, agriculture, and forests, has a host range that includes hundreds (thousands?) of species across many superfamilies. Fungal pathogens,

mostly in the Entomophthorales and Fungi Imperfecti, often require special conditions such as a period of high humidity before appreciable infection will occur. A species of special note is *Entomophaga maimaiga*. This fungal pathogen was introduced into North America from Japan in 1910 and 1911 as a biological control agent to stem the ever-increasing populations of the European gypsy moth (*Lymantria dispar*). The introduction was considered unsuccessful until 1989 when the fungus began showing up in caterpillar cadavers throughout the Northeast. It has since spread throughout much of the North American range of the gypsy moth and continues to be a principal mortality agent for the gypsy moth caterpillar. A diverse assemblage of nematodes and nematomorphans also attacks Lepidoptera, especially the larvae, but their importance is generally regarded as modest among nonsoil dwellers. Microsporidians affect both fertility and longevity in many moths.

Wolbachia are known from across the Obectomera and Heterocera, but infections likely occur across the order, given that some 25–75% of all insect species are known to be hosts to these endosymbiotic rickettsia-like bacteria (Kozek and Rao, 2007). In many species the cytoplasmic infections are passed vertically from mother to offspring (in the egg), whereas in others transmission occurs through sexual contact. The consequences of infection are both varied and complex, and adequate description is beyond the scope of this treatment. Known effects within the order include male-killing (through selective killing of male embryos); feminization, whereby genetic males are rendered into functional females; and egg–sperm cytoplasmic incompatibility (between sexual partners/mating strains). The nature of the infections is taxon-dependent, and ranges from entirely pathogenic and lethal (e.g., in those where males are killed) to symbiotic (e.g., some *Wolbachia*-infected insect lineages are reported to confer resistance to an array of RNA viruses and some pesticides). In *Phyllonorycter blandcardella* (Gracillariidae) (Figure 4) – a leaf miner of apple – *Wolbachia* infections maintain green tissues about the larval mine, even while the remainder of the leaf is yellowing, allowing larvae to complete their development before the host leaf senesces (Kaiser *et al.*, 2010).

Lepidoptera are primary hosts for a multitude of parasitoids. Three of the largest insect families on this planet owe much of their evolutionary success to the Lepidoptera: the Braconidae (> 10,000 species) (Hymenoptera), Ichneumonidae (> 10,000 species) (Hymenoptera), and Tachinidae (> 20,000 species) (Diptera). Another 20 or so families of insect parasitoids attack Lepidoptera, all but two of which (Diptera: Bombyliidae and Sarcophagidae) are parasitic hymenopteran wasps, mostly in Chalcidoidea and Proctotrupoidea. All four life stages are exploited by parasitoids, although most attack larvae. Typically only one or a few instars are attacked by a given wasp species. Most Hymenoptera are endoparasitoids that grow slowly initially, consuming only blood (hemolymph), their own nutritive cells released into the host, or nonvital host cells and tissues, then finish off the host in a burst of feeding and growth, often triggered by the host larva's size or hormonal state. In some cases this may be months after the wasp eggs were laid within the body of the caterpillar (see Wagner *et al.*, 2011 for a brief synopsis).

Some of the smallest insects, trichogrammatid and mymarid hymenopterans, with body lengths of only 0.2 mm, are egg parasites. A great majority of insect parasitoids are specialists that utilize but one or a few related species. Large, long-lived caterpillars support rich guilds of parasitoids: across eastern North America, 29 fly and wasp parasitoids are recorded from *Hyalophora cecropia*, at least three of which are believed to be specialists on this saturniid and its congeners. Large caterpillars may form the base of an entire food web, as evidently there are six hymenopteran hyperparasitoids that parasitize the parasitoids of *Hyalophora*, and one wasp hyperparasitoid that principally attacks the hyperparasitoids. Askew and others have noted that leaf miners and gall-forming caterpillars have an exceptionally rich parasitoid fauna. *Phyllonorycter apparella* (Gracillariidae) has a wingspan of only 7 mm, yet larvae and pupae of this leaf miner are known to host 20 species of hymenopteran parasitoids and hyperparasitoids.

Invertebrate predators of major importance include mites, spiders, predaceous stink bugs, beetles, robber flies, ants, and wasps. Many of the physical, chemical, and behavioral defenses of caterpillars are known to be effective in thwarting the pillages of ants (Figure 5). No doubt, these defenses are of special importance in tropical ecosystems where ants make up much of the insect biomass. Mammals, birds, reptiles, and amphibians are the principal vertebrate predators. Birds are such an important selection pressure for externally feeding caterpillars that there is a growing consensus that they have shaped not only what many caterpillars look like, but also what, when, and how they feed (Heinrich, 1993). Their influence on adult color patterns and behavior also seems to be pre-eminent. Bats, too, have been an exceptionally important evolutionary force in the diversification of the order. Hearing organs, sensitive to the frequencies emitted by bats, have evolved multiple times; within one of these groups, the Arctiinae (tiger moths), some chemically protected taxa have evolved the ability to signal back to bats. On detecting ultrasound frequencies, these moths begin clicking, presumably advertising their whereabouts (and toxicity). In addition, there is growing evidence that some can even thwart bats by jamming their echolocation sensory systems. Corcoran *et al.* (2009) have shown that *Bertholida* tiger moths employ a sound-producing tymbal located below the hindwing to generate ultrasonic frequencies that are sufficiently disruptive to cause bats to veer off course and abort their normal attack repertoire.

Defensive Chemistry

The defense strategies of Lepidoptera are legion and make for fascinating reading and study (see Bowers, 1993; Stamp and Casey, 1993; Scoble, 1992, for larvae and adults, respectively). All life stages may be chemically protected from at least a subset of the relevant natural enemies. Protected species (and life stages) tend to be aposematic. Many adult tiger moths (Figure 12) and the caterpillar of the monarch butterfly are dramatic examples; but even eggs and pupae of protected species may be rendered in warning colors. Adults of distasteful or otherwise toxic species are often diurnal and may be appreciably slower fliers than their unprotected sister lineage.

Figure 12 *Platyprepia virginalis*; chemically protected moths are often boldly colored and, like this species, diurnal.

Additionally, many tolerate rough handling (e.g., pinching) to a much greater degree than palatable species, a necessity of sorts because some fraction of the protected insect population has to tolerate or least survive the delivery of the noxious chemicals necessary to train the local predator complex (in each generation). Unpalatable species, as first pointed out by Bates (1982), frequently serve as models to one or more Batesian mimics or become entwined in Müllerian mimicry complexes.

Chemical defense against parasitoids and predators likely has played a prominent role in the diversification of the order. The ecological and evolutionary constraints facing unpalatable species differ widely from those faced by palatable taxa (Heinrich, 1993). For example, chemically protected caterpillars are often brightly colored, feed day or night, and rarely take measures to conceal their feeding damage; many are gregarious. Conversely, palatable species are apt to be cryptic in color, to be nocturnal, to move slowly, and to only rarely leave conspicuous signs of feeding. Across the order there is a spectrum of palatability, ranging from those species that can be eaten in large numbers (by birds or indigenous peoples) to those where contact or ingestion can be fatal. There is an enormous literature on this subject – this discussion and examples here are only meant to be illustrative.

Stinging setae, hollow and filled with poison, occur widely in hemileucine (Saturniidae), Limacodidae, Megalopygidae, and Zygaenidae. In rare instances, human fatality has been reported after encounters with the first and third. The body setae of *Euproctis chrysorrhoea* (Lymantriinae) (Figure 8) contain histamine, protease, lipase, and phospholipase, and are highly urticating and were perhaps responsible for two human deaths. (These cases may have resulted from severe allergic reactions or exposure and are regarded to be extraordinary. No human fatalities are known in recent times.) Gypsy moth caterpillars and other lymantriines drag the body setae through the dorsal abdominal glands, “arming” them with histamine and a diverse mixture of noxious substances that cause itching and other allergenic responses, which can be severe in some individuals. Other taxa with large numbers of species with urticating setae include the Arctiinae, Lasiocampidae, and thaumetopoeine Notodontidae (see review by Hossler, 2010).

In some lineages, caterpillars and adults synthesize noxious compounds from simple dietary precursors. Zygaenid larvae produce cyanoglucosides from two basic amino acids.

Chemical protection in many Notodontidae is based on simple manufactured compounds (e.g., the late instars of many Heterocampinae eject formic acid and ketones from a cervical gland if molested).

Other moths sequester toxins or precursors from their (poisonous) host plants; toxin concentrations in the hemolymph may greatly exceed those that occur in any of the plant tissues on which the caterpillar has fed. Examples include *Euphorbia*-feeding caterpillars, which retain dietary terpenols, and the milkweed caterpillar (*Euchaetes egle*) (Arctiinae), which, like the monarch butterfly caterpillar, sequesters high concentrations of a cardenolide. Other tiger moths (arctiines) actively seek out and consume host plants high in pyrrolizidine alkaloids (PAs). Experimental studies have demonstrated the effectiveness of PAs in repelling both vertebrate and invertebrate predators as well as their importance in courtship, mating, and paternal investment. If bright coloration can be used as a proxy for chemical protection, there is still a universe of protected moth species whose natural chemistry remains uncharacterized and unappreciated.

In many species the chemicals sequestered or manufactured by the caterpillars are retained by the adult. PAs collected by male *Utetheisa bella* (Arctiinae) caterpillars are used to synthesize the male courtship pheromone. Eisner and his students found that female *Utetheisa* (Figure 13) raised on diets devoid of PAs are readily consumed by spiders, but females that have mated with males laden with PAs are cut out and dropped from webs. The eggs and even young caterpillars, resulting from the latter type of pairing, are also chemically protected by the alkaloids collected by the father. Arctiines are not completely dependent on the larval diet because adults of some tiger moths are able to locate and ingest dissolved PAs. They will imbibe fluids from the surfaces or wounds of PA-containing plants (e.g., Asteraceae, Boraginaceae, and Fabaceae) or even the crushed bodies of alkaloid-rich caterpillars or moths. Many tiger moths bubble out a defensive secretion from the prothorax on disturbance.

Figure 13 Tiger moths (Arctiidae) (also see Figures 12 and 14). *Utetheisa bella*; in addition to sperm, the male transfers alkaloids during mating that protects not only his mate subsequently, but also her offspring.

In *Grammia*, the fluid is mostly clear and yellow to green and may represent nothing more than hemolymph (Figure 14); in others it is more frothy, sometimes milky, and loaded with acetylcholine, histamine, and possibly pyrazines. Adult female lymantriines collect larval hairs from the cocoon and incorporate these into their egg mass.

Not all pupae or adults retain the protection enjoyed by their larvae (e.g., adult saturniids and limacodids whose caterpillars are armed with stinging setae are generally palatable). Buckeye (Nymphalidae) butterflies whose larvae are protected by sequestered iridoid glycosides are palatable as adults, as much of their chemical arsenal is lost by the pupal stage.

Dispersal and Migration

Long-distance movements occur in many groups, not an insignificant number of which are pest species. Like birds, one of the most common patterns is for populations to cycle through the winter in tropical and subtropical latitudes, then to move north (or south) during the spring and summer. Some migrants move on the leading edge of storm fronts, where both high wind and high humidity facilitate long-distance dispersal. Occasionally moth numbers may be so great that they show up on radar screens. Swallows, swifts, and other insectivorous birds follow these fronts as well, gleaning insects as they go. A second common pattern is for moths to move between wet and dry forests, with adults trickling out of the latter over the course of the dry season then reinvading with the return of the rainy season. The dazzlingly beautiful sunset moths (Uraniidae) are famous for their mass diurnal migrations in Africa and Latin America.

Key Adaptations

One can only speculate as to why there are so many moths. One morphological feature that stands out as universal is the presence of scales over the wings and body. Those covering the

Figure 14 *Grammia virguncula*; adults of many tiger moths bubble out hemolymph, presumably laden with noxious substances, from their thoraxes when disturbed. Courtesy of Duncan Butchart.

wings are easily abraded, so much so that the wings feel slippery. Regardless of the context in which scales evolved, there can be little doubt that they provide considerable protection from natural enemies: adults can fly into a spider web and, if they are lucky, fly out, leaving behind hundreds of scales still attached to the web. Scales allow the wings to slide past one another and often out of the bill or jaws of a would-be predator.

The coillable siphon or proboscis has allowed Lepidoptera to exploit liquid diets (*see* Adults). More than any other feature, this structure has been tied intricately to the coevolutionary history of moths with flowers. Nearly all insect-pollinated flowers with deep corolla tubes (or nectar spurs) are pollinated by Lepidoptera. Charles Darwin knew this, and on being told of a Madagascar flower with a 25-cm corolla, predicted that a sphingid hawkmoth would one day be found on the island with a tongue of at least this length – and it was – and today bears the name *Xanthopan morgani praedicta*. The tongue also allows the collection of dietary constituents that are scarce in plants, such as nitrogen and sodium. No nonfeeding moths are known to migrate, suggesting that the presence of a tongue is a critical attribute for long-distance movement. Similarly all temperate moths that overwinter as an adult have a tongue.

A tympanum or analogous hearing structure, sensitive to the ultrasonic frequencies used by hunting bats, has evolved independently in no less than five nocturnal moth lineages (Scoble, 1992 and Figure 15). It may be no coincidence that three of these (the Geometroidea, Noctuoidea, and Pyraloidea) are among the most species-rich moth clades. Fenton and Fullard estimated that 85% of all macrolepidopterans possess some type of hearing organ. Noctuids that detect ultrasound first attempt to fly away from the source, but if the hunting frequencies are sensed at close range, these moths either drop to the ground or initiate a highly erratic flight while spiraling downward. Further testimony as to the importance of the ear is provided by the mites that infest the tympanal cavities of certain noctuids (especially *Leucania*) (Figure 15). Treat found that mites placed onto *Leucania* always move into one ear, leaving the other fully operational.

Figure 15 “Ear” of *Leucania* (Noctuidae) located below hindwing (head to right). Courtesy of Asher Treat.

Silk has played a major role in the evolutionary success of the order. Widespread use is seen in the formation of the cocoon or in the attachment of the chrysalis to the pupation substrate. Most microlepidoptera use silk to form a shelter or to line a chamber within the larval feeding substrate. Some caterpillars lay down silk whenever they walk, which presumably allows them to quickly retrace their path, for example, in times of danger. Case making, where the caterpillar constructs a portable silken case, has evolved in no less than a dozen moth groups; two especially successful lineages include the Psychidae and Coleophoridae (both families are appreciably more species rich than their noncase-making sister taxon). Some gregarious caterpillars spin conspicuous nests. Not only do these nests offer protection from natural enemies, but they can also be important in thermoregulation, heating up well above ambient temperatures on cool days (Fitzgerald, 1995). Many species, especially among those taxa with flightless females (e.g., some Psychidae, Geometridae, and Lymantriinae), disperse by “ballooning.” Early instars drop from silken lines and wait for winds to blow them about. Among microlepidopterans, it is common to see prepupal larvae dropping from trees on silk lines on their way into leaf litter where pupation will occur. At night many geometrid caterpillars drop from their perches, suspended on a silken thread, and dangle for hours before climbing back onto foliage, always before daylight. In a similar fashion many caterpillars, if disturbed, drop from their perch on a silk belay and crawl back up after the danger has past. Processionary caterpillars (Notodontidae: Thaumtopinae) and tent worms (Lasiocampidae) lay down a silk trail, impregnated with pheromone, that siblings follow. Some microlepidoptera (e.g., Bucculatricidae) form a molting cocoon within which the vulnerable transition between instars takes place. Prior to molting, many species lay down a light sheet of silk into which the crochets are engaged; this allows the new instar to crawl more easily out of its old integument.

One behavioral trait that stands out is the ability of Lepidoptera to exploit the hours of darkness. In terrestrial ecosystems moths are the most diverse and numerically important group of nocturnal flying insects. Perhaps 90% of all Lepidoptera are night active. Associated with their nocturnal habits is the order’s remarkable elaboration of morphological, neurophysiological, and behavioral traits that facilitate pheromonal communication (*see* Pheromones).

The extraordinary evolutionary and ecological success of moths may also be a matter of being in the right place at the right time. Because the order was essentially phytophagous and beginning to diversify on nonseed plants and gymnosperms prior to the origin of angiosperms, moths were well poised to ride along with the explosive radiation of flowering plants that was to follow in the Cretaceous. Indeed, the Lepidoptera are the largest single (monophyletic) lineage to have co-diversified with plants (Strong *et al.*, 1984; Menken *et al.*, 2010).

Pheromones

While visual communication is thought to be of modest importance in nocturnal moths, chemical communication is highly developed and quintessentially important to most.

Figure 16 *Hemileuca maia* (Saturniidae); receptive females expose an abdominal gland – here, the small orange structure at the tip of the abdomen, extended nearly perpendicular to the body axis – when “calling” for males. The morphology and location of the sex pheromone gland(s) vary considerably from family to family.

The first animal pheromone was identified from the Chinese Silk Moth (*B. mori*) and was appropriately dubbed bombykol. In nearly all nocturnal moths, virgin females release a pheromone that attracts males from distances of up to several hundred meters (reports of up to a mile are likely exaggerated) (Figure 16). Males move upwind, in and out of the pheromone plume, until they arrive at its source. The male antenna and associated neurophysiology make up one of the most sensitive chemical detection systems known in nature. Not surprisingly, males often have more elaborate antennae than females, sometimes with secondary or tertiary branches that increase the surface area several fold (e.g., many bombycoids, Figure 17). One interesting exception, and one that remains unexplained, are *Arrhenophanes* females (Tineioidea) – the female’s antenna is considerably more complex than that of the male.

Female sex pheromones usually are released from glands on the abdomen, often located in the intersegmental regions between abdominal segments seven and eight or eight and nine. The sex pheromone typically contains a “cocktail” of two to several volatile compounds, usually with one or two major components that are responsible for most of the male attraction. The individual components of the pheromone are often odorless. Structurally they tend to have a straight-chain hydrocarbon backbone, one or more double bonds, and an active moiety (e.g., an acetate, aldehyde, epoxide, ketone, or alcohol). Closely related species tend to have different

Figure 17 *Antheraea polyphemus* (Saturniidae); male saturniids have strikingly plumose antennae that contain thousands of setae, which capture female sex pheromone molecules.

Figure 18 Male scent-releasing structure of *Trichoplusia ni* (Noctuidae); end view of abdominal brush that encircles the male genitalia. Courtesy of Ken Haines.

(enantiomeric or isomeric) blends, minor components, or “calling” times.

Once the two sexes are in proximity, a panoply of male courtship pheromones frequently come into play. The structures by which males deploy their pheromones are as varied as any structures in the order. In the simplest case they are merely individual scent scales peppered over the wings or other parts of the body. Male sex scales (or androconia) that are grouped into tufts, brushes, or “pencils” occur over almost any part of the body including the wings, legs, mouthparts, and antennae. They are especially common about the genitalia, where they provide final signals prior to coupling (Figure 18).

Remarkably complex scent organs occur in a number of hepialids and various noctuoids (e.g., arctiines and herminiine erebids) (Figure 19) and others. A hallmark of androconia is

Figure 19 *Estigmene acrea* (Erebidae: Arctiinae); “calling” male with fully extended coremata (eversible sacs) lined with scent scales. Courtesy of Mark Willis. Reversed calling, with males broadcasting a primary sex pheromone to which females must orient, such as exhibited here by *Estigmene acrea*, is very rare among moths. Courtesy of Mark Willis.

that their abundance and development may differ markedly among closely related species, which suggests that they are under strong sexual selection (and maybe energetically expensive). They tend to be frequent as well as morphologically elaborated in genera where two or more species co-occur, especially if a common host plant is shared.

Male pheromones are thought to serve in species recognition and isolation and to promote female acceptance. In general, they are used at close range in the vicinity of the female. Role reversal, with males calling females from downwind, is very rare but does occur (e.g., see [Figure 19](#)). Chemically, male pheromones are exceptionally heterogeneous, ranging from simple molecules to long-chain hydrocarbons and ring compounds. Many have a detectable and often pleasant odor. The male pheromone blend of the oriental fruit moth contains both (Z)-methyl epijasmionate and (E)-ethyl cinnamate; the former is the active constituent in the odor of jasmine, a common ingredient in women’s perfumes. Many male scents are based on secondary plant compounds that are sequestered by the larva or collected by the adult. In some arctiines, the female is reluctant to copulate with males that lack appreciable quantities of PAs on their androconia.

Beyond mate location, courtship, and mating, pheromones are also known to serve in a number of lesser roles. Some female moths (e.g., yucca moths) leave behind a marking pheromone at the time of oviposition that alerts other females that the resource is already “in use.” The aggregation behavior displayed by some arctiines and noctuids is likely mediated by pheromonal signals. During mating, some male Lepidoptera transfer an “antiaphrodisiac” pheromone to the female that, at least temporarily, repels other would-be suitors.

Coloration, Diurnality, Nocturnality, and Attraction to Light

As a general rule, moths that are active principally at night are subtly colored in earth tones, especially browns, grays, black,

and white. The patterning in nocturnal taxa is often variable, presumably because details of the coloration are under relaxed selection pressure. But exceptions to both of these statements abound. Most notably, there are dozens of lineages with brightly colored hindwings that are covered by cryptically colored forewings, with the bright colors and bold patterning being exposed as a flash signal after a moth has been discovered. A principal advantage of such coloration being that the stimulus can be immediately concealed (and therein lost) once the moth alights and again covers the hindwings with the drably rendered forewings. Bright fore- and hindwing coloration is associated with moths that are diurnal or both diurnal and nocturnal.

It is evident that diurnality has evolved repeatedly, perhaps hundreds of times within the order. The most conspicuous example is that of the butterflies, which are, from an evolutionary sense, nothing more than a group (or two) of diurnal moths. Taking the Geometridae as a focal taxon, there are dozens of species and genera that are diurnal; yet there are essentially no species-rich clades (tribes and subfamilies) within the family that are active principally during the day. Diurnality is common among moths that live in alpine or arctic habitats or that fly during the coldest months of the year, as well as that are chemically protected.

From a phylogenetic perspective, diurnality is well distributed across the order. Members of the most basal family, the Micropterigidae, are both diurnal and nocturnal in habit, with some genera exhibiting splendidly metallic golds and reflective purples. These same bright colors are found in a host of other primitive families (e.g., Heterobathmiidae, Eriocraniidae, and Incurvariidae). Like in the Micropterigidae, adults may be active both day and night. Across the Microlepidoptera diurnality is widespread; important diurnal lineages include the Adelidae, Choreutidae, Heliodinidae, Heliozelidae, Scythrididae, and Sesiidae. Many moths are crepuscular, some flying at both dawn and dusk and others limiting their activity to one of these two periods of rapidly changing light intensities.

Nearly all nocturnal moths can be collected at light. Indeed, light traps are routinely employed to conduct moth inventories, to monitor populations of agricultural pests, and to collect gravid females for life history studies. The most commonly asked question about moths is “Why are they attracted to light?” Surprisingly the question has never been answered definitively. One common explanation that has almost no empirical support is the moon-compass explanation. It goes like this: If a moth had a need to fly in a straight line at night it could do so by maintaining a constant angle to any celestial light source. When this same behavior (constant orientation to a distant light source) is applied when a light is proximate, a moth will spiral into a nearby light source ([Figure 20](#)). And while seemingly logical and compelling, it is rare that a moth spirals into a light – more often the flight path is erratic but directed. An equal mystery is why only a fraction of the moths present in a given area are attracted. Anyone who runs flight interception traps, collects at bait, or knows what caterpillars are feeding in the garden appreciates the fact that the individuals attracted to light represent only a fraction of the whole. Sex ratios in light-collected samples are often heavily biased toward males. Hepialids in the genus *Sthenopsis*

(a)

(b)

Figure 20 A moth can proceed in a straight line by moving at a constant angle (a) to a distant light source. However, if the light is proximate, (b) this same orientation behavior will cause the moth to spiral into the source. Reproduced from Evans HE (1984) *Insect Biology. A textbook of Entomology*. provide a counterexample as females predominate in museum collections. There are many moths known primarily from one sex – the sex that is attracted to light. Many of the moths thought to be rare by collectors are simply among those that are not attracted to light with great frequency.

Moths are not entirely dependent on celestial navigation. There is ample evidence that moths also possess a geomagnetic

compass that allows them to move in a directed fashion, even on moonless nights and under overcast skies.

Importance

Lepidoptera, in particular moths, are among the most important forest and agricultural pests. There is almost no plant tissue that is not eaten by one or more species of moths. Most of the forest pests are of cyclical occurrence with natural enemies eventually controlling population numbers. Introduced species offer an obvious exception to this generalization – their populations may go unchecked for many years before natural enemies are introduced or recruited from the native fauna. Agricultural pest moths have plagued farmers for millennia. As noted earlier, many are migrants, preadapted to be crop pests (because they are highly dispersive insects that locate resources quickly and thrive in early successional habitats). Additionally, crop pests often have short life cycles that allow them to complete one or more generations before natural enemies can build to appreciable numbers. A species, such as the Indian Meal Moth (*Plodia interpunctella*) (Pyralidae), are important stored product pests that attack grains, cereals, bird seed, dry dog food, and even candy that has sat too long. Clothes moths (*Tinea* and *Tineola* species) (Tineidae) are well known for their ability to damage woolens.

Most moths should be regarded as beneficial principally for their role in terrestrial food webs, especially those that include birds, bats, and rodents. Many songbird nestlings are dependent on caterpillars. With the exception of large, bat-pollinated flowers, most white-flowered plants are pollinated by moths under cover of night. Scents from moth-pollinated flowers may be exceptionally fragrant (e.g., honeysuckle, jasmine, and some orchids). Sphingidae are the primary pollinators for about 6–8% of the tree species in Costa Rica's seasonal dry forests. These large, strong fliers are especially important in tropical forests where individuals of the same species can be widely spaced. Many moth caterpillars feed on leaf litter, decaying wood, and fungi and thus play at least a minor role in litter decomposition and nutrient cycling, such is especially true in the eucalypt woodlands and forests of Australia. The most famous product derived from a moth is silk. This fiber, with a tensile strength greater than that of steel, is still made the same way it has been for more than 4600 years by boiling the cocoons of *B. mori* and unraveling them a single thread at a time. Moths have been used successfully as biological control agents of invasive weeds. Australia had lost 50 million acres of pastureland to introduced prickly pear cactus (*Opuntia*) before the pyralid, *Cactoblastis cactorum*, was introduced from southern South America. Within a decade of its release, most large stands of exotic cactus had been utterly destroyed. The moth also has been effective in controlling invasive *Opuntia* in Hawaii, Mauritius, South Africa, and the West Indies. This story recently has taken an unfortunate twist, as this same moth has found its way into the Florida Keys, where it now threatens stands of three rare (native) species of *Opuntia*. Moreover, the moth has since spread westward to Louisiana and it is feared that it will soon reach the American Southwest and Mexico where *Opuntia* is an ecologically and economically important plant. In Mexico, prickly pear is a

food source for both humans and livestock. In deserts and other xeric communities, dozens of species of vertebrates and invertebrates are reliant on *Opuntia* stands for both food and shelter.

Conservation

Across much of Europe and the USA, lepidopteran faunas are increasingly used as bioindicators by state, provincial, and federal agencies and nongovernmental conservation organizations to evaluate natural areas and management regimes. Moths offer many advantages as bioindicators: most temperate macrolepidopterans are easily identified and their habitat requirements are reasonably well known. By any standard they are hyperdiverse and therefore provide considerable data relative to the amount of effort that goes into their sampling and sorting. Part of their value as bioindicators is that they represent another trophic level – two grasslands that are botanically equivalent would have different moth faunas if one were being managed too intensively (e.g., by fire). One disadvantage of moths as bioindicators is that samples often include many transients. For example, more than one-third of the species of moths that occur in Denmark have been collected in a light trap atop the Zoological Museum on the University of Copenhagen campus at the periphery of the city.

The principal threat to moths is the same as for other terrestrial invertebrates – habitat destruction and fragmentation – this is especially true for tropical forests where moth diversity is thought to be highest. In some ecosystems, reforestation and succession pose threats to moths. Fire suppression in grasslands, chaparral, barrens, scrub forests, and other fire-maintained ecosystems has been detrimental to many local invertebrate populations. And the reverse, ill-timed and too aggressive prescribed burning, can greatly diminish Lepidoptera populations. There has been much discussion about the impacts of artificial lighting on moth populations, much of it focusing on the decline of saturniids and other large moths. Up to this point the published commentary has been anecdotal, but there can be little doubt that street lamps and other high-intensity lamps have had some impact on moth populations – within days, bats learn to forage at them by night, and they are among the first places that birds visit at dawn.

Introduced or alien species can be a threat at many levels. Invasive plants can displace native hosts on which either the larvae or the adults of native moths depend. In exceptional cases, introduced plants can provide strong ovipositional cues for species whose larvae either fail entirely or experience high levels of mortality. Exotic species, be these pathogens or herbivores, that threaten native hosts, can have grave consequences. The loss of American chestnut to an introduced fungal blight is thought to have brought about the extirpation of five native moths. If the emerald ash borer beetle – an introduced cambium feeder from East Asia that kills species of *Fraxinus* – continues unabated, as many as two dozen species of North American butterflies and moths could fall as collateral victims (Wagner and Van Driesche, 2010). Because introduced moths often arrive without natural enemies, their numbers can cause widespread overexploitation of host

plants. The widespread defoliation events following introduction of the gypsy moth (*L. dispar*) presumably have had some local impacts on native species. Top-down threats from the release of introduced predators, pathogens, and parasitoids for biological control efforts merit special attention. The tachinid, *Compsilura coccinata*, was introduced from Europe into eastern North America to control the gypsy moth. The parasitoid's host range includes more than 200 native species. The moth has one generation a year, the fly three to four. It has been estimated that a single acre of a gypsy moth infested forest will yield up to 10,000 adult *Compsilura* in June, which then must seek out alternate (native) hosts.

Although DDT and other pesticides have been implicated in the local extirpation of Lepidoptera, the evidence is invariably circumstantial. Although suppression activities (single applications) would rarely be expected to result in local extinctions, eradication efforts (multiple applications, especially in a single season) certainly impact moths and the insectivorous animals that are dependent on them. The most widely used biological pesticide to control Lepidoptera is *B. thuringiensis* var. *kurstaki* (Btk) – a bacterium that either kills a caterpillar outright or leads to a systemic infection that results in death. Btk is used by home owners to control garden pests, by farmers in agricultural systems, and by government and industry to combat forest defoliators. Product labels indicate that Btk is effective against a taxonomic array of Lepidoptera (and Coleoptera). Susceptibility to Btk ranges from taxa that are not affected to those that are killed weeks after a single application; saturniids and papilionids (swallowtail butterflies) are among the groups reported to be especially susceptible. From one perspective, Btk is a great control agent because it affects few nonlepidopterans and has no mammalian or avian toxicity. Yet from a lepidopterists' perspective it is hard to view Btk in such a positive light. The use of Btk and other pesticides in natural ecosystems is most likely to be a problem over critical habitats that are isolated, restricted, or in some other way imperiled, especially when these occur within a matrix that contains a primary pest. For example, the glades, balds, or barrens communities that occur in an otherwise forested landscape are apt to suffer from the aerial pesticide applications targeted for forest pests. Routine transgenic manipulations in agricultural systems may also prove to have wide-reaching consequences. It appears that no less than three cotton-feeding moths, which originally fed on native cottons, are slipping toward extirpation in North America.

Climate change may be the most significant planet-wide threat to moths, especially to those that dwell in isolated (e.g., islands and mountains tops) or relict (bogs and inland dunes) areas, where successful active or passive movement between suitable habitats patches is unlikely. Significant changes in temperature and precipitation patterns will be a challenge for species worldwide, especially for those taxa that are stenotopic or otherwise occupy specialized niches.

With the exception of the Chinese silk moth, which no longer exists in the wild, there is little evidence that collectors have ever represented a significant risk to moths. Collecting is likely to represent a threat only to highly imperiled and geographically restricted taxa. Where population sizes are very small, the use of light traps that employ a killing agent should be avoided. Paradoxically, a greater threat may be

undercollecting, as it seems probable that only about half of the world's moth fauna has been described. And even in those regions where most of the basic taxonomic work has been completed, it is not until we have extensive and taxonomically reliable occurrence data on a broad geographic scale that conservation biologists will know with certainty which species are increasing, which are stable, and which are slipping toward extinction.

Several British studies report significant declines in moth and butterfly abundance and diversity over the past three decades (e.g., Asher *et al.*, 2001; Conrad *et al.*, 2006). A recent status survey for larger moths in the Netherlands concluded that one-third of the fauna showed signs of decline, even among many common taxa, and suggested that climate change may be at the root of many of the losses (Groenendijk and Ellis, 2011). Across the Northeastern USA and southern Canada moth collectors and taxonomists are reporting declines, especially among Saturniidae, Sphingidae, and Noto-dontidae. If such declines continue there will be downstream consequences to dependent birds, mammals (especially bats), parasitoids, and sundry others. There is an urgent need for multi-year data sets that can be used to quantitatively document the taxonomic scope, geographical extent, and the ecological magnitude and consequences of moth declines.

Glossary

Anthropochoric Geographic distribution due to human agency.

Cerotegument Hydrophobic secretion layer covering the body of several arthropods adapted to temporary submersion.

Disharmonic, fauna A fauna in which a strongly reduced number of major lineages is represented, as in oceanic islands, due to their improbable colonization from distant sources.

Laurisilva Warm-temperate woodlands characterized by evergreen broadleaves such as laurel (*Laurus*) trees.

Pupoid Earliest postembryonic stage with incompletely developed appendages, as in insect pupae, hence motionless.

Stenotopic A species (or higher taxon) with a highly restricted geographic range.

Introduction

Myriapods are wingless terrestrial arthropods with at least nine pairs of walking legs in the adult and a trunk not subdivided into thorax and abdomen. Most myriapods begin their post-embryonic life with a small number of trunk segments and leg pairs, and obtain the remaining ones through a series of molts. However, no myriapod undergoes a complete metamorphosis as many insects do in their life cycle. These and other features of myriapods have long been regarded as primitive within a large arthropod lineage called the Atelocerata (or Tracheata, Uniramia, or Labrata), traditionally recognized as including myriapods and hexapods, as opposed to the other main arthropodan lineages Chelicerata and Crustacea. However, molecular investigations suggest that insects may be closer indeed to crustaceans than to myriapods, a scenario that invites fresh reinvestigation of the real affinities of the myriapod groups among themselves and to the remaining arthropods. Some studies even suggest that myriapods form with the chelicerates a natural group, the Paradoxopoda or Myriochelata. Irrespective of their eventually closer affinities to the insects and crustaceans or to the chelicerates, myriapods are mostly reported as forming a natural (monophyletic) group (Edgecombe, 2011), supported by morphological characters (e.g., Edgecombe, 2004) as well as by molecular evidence (e.g., Regier *et al.*, 2010).

Four recent and a few fossil classes of myriapods are recognized. Centipedes (class Chilopoda) and millipedes (class Diplopoda) are the main myriapod groups, whereas the two remaining recent classes, the Symphyla and the Pauropoda, lack vernacular names. Of the extinct myriapodous arthropods, Kampecarida are among the most remarkable, because they possibly represented the earliest myriapods ever (Upper Silurian), although it is still debatable whether they were terrestrial or not. The extinct Archipolypoda and Arthropleurida were possibly true Diplopoda; the former were conspicuously spiny and reached 30 cm in length, the latter contained both the smallest (a few millimeters) and the largest myriapods ever (up to 3 m long). Remains of the several other extinct orders are also known from

the Paleozoic. Apart from some problematic Silurian remains that have been tentatively interpreted as scutigermorph legs, the earliest centipedes recorded are the extinct Devonobiomorpha from the Devonian.

Basic Morphology

Chilopoda

Centipedes range in length between a few millimeters and the approximately 30 cm of *Scolopendra gigantea* (Figure 1). The centipede body is divided into head and trunk. Compound eyes are only present in Scutigermorpha, whereas groups of simple eyes (ocelli) are present in most Lithobiomorpha and many Scolopendromorpha; all Geophilomorpha and many Scolopendromorpha are blind, as are several cavernicolous representatives of the Lithobiomorpha. The antennae may be longer than the body, as in the Scutigermorpha and in some Lithobiomorpha. In these two groups, the number of antennal articles is mostly high and variable, but it is fixed and generally lower in the other groups (14 in all Geophilomorpha and 17 in most Scolopendromorpha). The first trunk segment bears a pair of specialized appendages – the poison claws (or forcipules), each of which contains a poison gland – which are used in the capture of prey and occasionally in defense. Each of the following segments bears a pair of legs, mostly of cursorial type, often with sexual or other specializations in the last pair(s). Curiously, the number of leg-bearing segments is always odd-numbered in the adults, with 15 pairs of legs in all Scutigermorpha, Lithobiomorpha, and Craterostigmomorpha, but 27 (*Schendyllops oligopus*) to 191 (*Gonibregmatus plurimipes*) in the Geophilomorpha. In most geophilomorph centipedes, to the exclusion of the vast majority of the Mecistocephalidae, the number of trunk segments is variable within the species and higher in females. Nearly all species in the Scolopendromorpha have either 21 or 23 pairs of legs, but one species (*Scolopendropsis bahiensis*) includes individuals with 21 as well as individuals with 23 pairs of legs, and its closest relative, the recently described *Scolopendropsis duplicata*, includes individuals with 39 and individuals with 43 pairs of legs (Chagas *et al.*, 2008).

Figure 1 Habitus of representatives of the four main centipede orders: (a) *Scutigera coleoptrata* (Scutigeroidea); (b) *Geophilus carpophagus* (Geophiloidea); (c) *Scolopendra cingulata* (Scolopendroidea); (d) *Lithobius validus* (Lithobioidea). Adapted from Centre International de Myriapodologie.

Unique to the Scutigeroidea is a respiratory system with seven dorsal openings providing oxygen to the dorsal vessel via thick bundles of tiny, short tracheae; the oxygen is further distributed to the whole body with the help of the circulatory apparatus: the circulating liquid (hemolymph) contains

an oxygen-binding pigment (hemocyanin) related to the respiratory pigments found in several chelicerates (scorpions and spiders) and crustaceans. In all the remaining centipedes there are tracheae comparable to those of insects, opening on lateral spiracles of most trunk segments (Geophiloidea

and the scolopendromorph genus *Plutonium*) or on alternate segments (the remaining groups). The genital opening is found on a subterminal segment at the posterior end of the body, near the anus.

Centipede stings are fairly frequent, but usually do not represent a mortal event for humans. In literature there are only a few well-documented cases of death caused by these animals. Nevertheless, several species may cause serious damage in humans, including myocardial ischemia and infarction, hemoglobinuria and hematuria, hemorrhage, and rhabdomyolysis. Also allergy-like complications have been recorded following centipede envenomations. Most centipede envenomations, however, produce transient symptoms that can last a few days but do not require acute medical treatment (Bush *et al.*, 2001).

Information on venom composition is available only for a few species of scolopenders, their venom is a mixture of toxins including myotoxins, cardiotoxins, neurotoxins, cytotoxins, together with several enzymes like esterases, proteases, and hyaluronidases (Undheim and King, 2011).

Some scolopenders have found a place in traditional Chinese medicine alongside scorpions and other arthropods.

Diplopoda

The size of millipedes spans between a few millimeters and 35 cm, one of the largest species being the spirostreptid *Sechelleptus seychellarum*. The body (Figure 2) includes a head and a trunk. Groups of simple eyes are present in most orders but are lacking in all Polydesmida and in some other groups as well as in all specialized cavernicolous species. The antennae are generally short and always comprise only eight articles. The mouthparts are generally adapted for cutting and chewing hard matter, such as wood or dead leaves, but some millipedes have evolved adaptations for sucking. The trunk is normally elongate, more or less flattened dorsoventrally, but subcylindrical in several orders. The body wall is rarely soft and flexible (subclass Pselaphognatha with the only order Polyxenida) and the exoskeleton is usually rigid (subclass

Figure 2 Habitus of representatives of the main millipede orders: (a) *Macroxenus enghoffi* (Polyxenida) (after Nguyen Duy-Jacquemin, 1996); (b) *Polydesmus* sp. (Polydesmida); (c) *Brachycybe* sp. (Platydesmida); (d) *Opisthocheiron canayerensis* (Chordeumatida); (e) *Trachysphaera lobata* (Glomerida); (f) *Stemmiulus adisi* (Stemmiulida). Adapted from Centre International de Myriapodologie.

Chilognatha, with all remaining orders) due to the presence of calcium salts in the internal layers (endocuticle). When the millipede is about to undergo a molt, these salts are dissolved. Accordingly, these arthropods need to obtain from the food sizable amounts of calcium. There are no waxes in their epicuticle, but some protection from evaporation is obtained through the lipid compounds in their exocuticle.

The first trunk segment (the collum) is legless; it is followed by three (four in the Spirobolida) "thoracic" segments with one pair of legs each and a further number, sometimes very high, of "abdominal" segments with two pairs of legs each. There are 11–17 pairs of legs in the Polyxenida and at least 17 (but usually many more) in the remaining groups, with the highest number being 375 pairs of legs recorded in *Illacme plenipes* (Enghoff, 1990).

Most millipedes are provided with chemical defenses in the form of glands (ozadenes) producing noxious substances which pour out from the series of repugnatorial openings (ozopores), dorsal in the pill millipedes (Glomerida) but lateral in the majority of the diplopods. No chemical defense has been detected in some lineages, that is, the Polyxenida, the Sphaerotheriida, and the Chordeumatida.

A few millipedes spray their secretions up to 40 cm. These secretions are quite effective against both the vertebrates and arthropods. Warning colors are widespread.

The repugnatorial secretions of several large millipedes appear so noxious that some Indian tribes in Central America use them for poisoning arrows prior to hunting. However, some of these tribes cook large millipedes and find them tasty.

A diversity of defense substances have been found in these animals, with distinct classes of chemicals being characteristic of the different millipede groups: The juloids rely on benzoquinones, hydroquinones, phenol, and the acetates of some long-chain carboxylic acids; the polydesmoids rely on several carboxylic acids but especially on benzoic acid, benzaldehyde, hydrogen cyanide, and mandelonitrile; and the pill millipedes (Glomerida) rely on very peculiar and complex heterocyclic compounds (glomerin and homoglomerin) and the Polyzonida on compounds known as polyzonimine and nitropolyzonimine (Eisner *et al.*, 1978). Several millipedes are adapted to coiling onto themselves (volvation), thus becoming a smooth ball difficult to seize; many others can roll themselves into a spiral flat coil. However, despite such precautions, many millipedes fall victim to insectivorous birds and predatory arthropods.

Special modifications of one or two (more rarely, three or four) leg pairs in the male may involve their transformation into clasping or genital organs. Posterior claspers are characteristic features of the Pentazonia (the pill millipedes and their closer relatives). The male uses these claspers to fix the female during mating. In the males of most other millipedes, one or, more commonly, two leg pairs of body segment 7, or of segments 7 and 8, are modified into gonopods. These are mostly very complex structures directly involved in sperm transfer. The use of the fifth pair of legs of the male *Chelojulus sculpturatus*, which are transformed into functional forceps, is unknown.

The tracheal respiratory system is provided with spiracles normally opening on the sternum near the coxa. The paired

Figure 3 Habitus of (a) a symphylan and (b) a pauropod. Adapted from Centre International de Myriapodologie.

gonopores open on the coxae of the second pair of legs or in their proximity. Those of the male are found on a special structure incorrectly termed penis, which has nothing to do with direct sperm transfer.

Symphyla

Symphylans are tiny myriapods, mostly 2–9 mm long (but *Hanseniella magna* is 25–30 mm long), generally with a whitish body (Figure 3(a)). All species are blind and bear one pair of elongate multisegmented antennae, 12 (rarely 11) pairs of legs, and a pair of posterior unarticulated appendages called spinnerets. The mouthparts are of masticatory type. The genital opening is found on the fourth trunk segment. Symphylans are the only arthropods with a pair of respiratory openings on the head, but the whole of their very soft and permeable cuticle is important for gas exchange. In these tiny myriapods there is no cuticular protection against evaporation.

Pauropoda

Pauropods are the smallest among myriapods; most species are only 0.5–0.7 mm long, and the largest is just 2 mm long (Figure 3(b)). There are no eyes. The antennae are of unique structure, with four (order Tetramerocera) or six (order Hexamerocera) basal articles and two apical or subapical branches, each bearing in turn one or two flagella. The mouthparts are comparable to those of millipedes but are generally adapted to the suction of fluid aliment. The trunk bears 9–11 pairs of legs. Most species lack a respiratory system; one pair of tracheae, with spiracles on the coxae of the first pair of legs, is present only in the Hexamerocera.

Basic Biology

Nearly all myriapods are strictly terrestrial and most species are found in forest leaf litter or in rotten wood, under the bark of dead trees, in the soil, or in caves. Several millipedes also occur in dung, compost, and almost any other kind of plant debris; in nests of ants, termites, and birds; in worm and mammal burrows; near water; on the seashore; on open terrain; under stones; in buildings; etc. That is, they are found in virtually any terrestrial environment.

A few species of diplopods (e.g., *Blaniulus guttulatus*) and symphylans (*Scutigera immaculata*) are agricultural pests. Owing to their swarming habits, a few millipedes can be of danger for transport when smashed in myriads on roads or railways or for housing, especially due to their smell, but such extremes are exceptional. In temperate regions, migrating swarms of many thousands of millipedes have been recorded, especially swarms of polydesmids (e.g., *Fontaria virginiana*, *Parafontaria laminata*, and *Polydesmus collaris*). Causes for and mechanisms of this behavior are little known, but it has been suggested that heavy rainfalls may cause the swarming behavior of a large spirostreptid (*Plusioporus setiger*) in southern Brazil. Larger millipedes have quite long life spans lasting between 2 and 11 years, whereas their life histories usually take 2 or 3 years even in tropical environments. In high-montane habitats, the development is normally retarded by a year or two. However, some tiny tropical species live for less than 1 year and their life cycle takes only about 3 months.

Among myriapods, only some centipedes have successfully colonized eremic environments, with many species of this class (mostly belonging to the Scolopendromorpha) being true deserticoles. This is due to their structural adaptations (waterproof cuticle or complex spiracles) allowing them to reduce water loss. The remaining myriapods are distinctly hygrophilous to mesophilous, often (the bulk of millipedes) calciphilous as well, which explains their difficulty in coping with conditions differing from those prevailing in forest litter.

Tree dwellers are not common among myriapods, being mainly represented by small or slender, if not flat-bodied, millipedes and by some representatives of lithobiomorph and geophilomorph centipedes. Species confined to the tree crowns or living in suspended soil are even fewer. Some scolopendromorphs, however, are fairly common in suspended soils in the tropical forests of America.

Within the Chilopoda, only the Geophilomorpha include halophilous species such as *Tuoba poseidonis*, *Strigamia maritima*, *Hydroschendyla submarina*, and *Geophilus seurati*. *S. maritima* feeds on crustaceans (amphipods and barnacles) and gastropods (the periwinkle *Littorina saxatilis*) (Barber, 2009).

Centipedes are often found in the nest of ground-dwelling mammals, e.g., moles and field mice. Their presence in such specialized environments is likely opportunistic, in the majority of cases, but a distinct preference for mammal nests has been claimed at least for the lithobiomorph *Lithobius crassipes* and the little scolopendromorph *Cryptops hortensis*. Also facultative seems to be the presence of millipedes and centipedes in ant and termite nests, where these arthropods, especially lithobiomorphs, are apparently well tolerated by their hosts.

Myriapod species capable of tolerating sea water are particularly few, although these are often quite common and

widespread. Interestingly, no conspicuous morphological types can be discerned among myriapods as obvious adaptations to any of such definitely marginal environments. Again, no common morphological adaptation is shared by the relatively few anthropochoric myriapods that have attained more or less vast, sometimes worldwide, distributions due to human agency. However, several minor modifications of leg structure can be assumed as advantageous for better climbing performance, whereas other adaptations involving the mouthparts and spiracles indicate the species' semiaquatic habits (Adis *et al.*, 1998; Golovatch and Kime, 2009).

In their feeding habits, myriapods are quite diverse. Centipedes, as revealed by their poisonous forcipular fangs, are basically predatory. They are mainly solitary hunters; gregarious habits have rarely been observed, including feeding on barnacles by swarms of specimens of the geophilomorph *S. maritima* in the tidal region along the seashore. Some centipedes, however, are known to occasionally consume plant material. In contrast, most millipedes feed on vegetable matters, particularly dead leaves and wood, but also algae, fungi, lichens, moss, and pollen.

Of recent, somehow unexpected records have noticeably enlarged the prey range of scolopendromorph centipedes (Voigtländer, 2011). This is now known to include scorpions (the European *Scolopendra cingulata* preying on *Euscorpis flavicaudis*), bats (*Sc. gigantea* on a Venezuelan bat species), tree frogs (*Otostigmus tibialis* on *Dendropsophus elegans*), and even sea anemones (*Otostigmus scabricauda* on *Bunodosoma caissarum*).

Millipedes, whose density in forest soil is sometimes higher than 1000 individuals per square meter, are estimated to consume 10–15% of the annual leaf fall in temperate forests. A few species may be qualified as omnivores; very few are carnivores – one of them being *Apfelbeckia insculpta* (order Callipodida), which feeds on earthworms. Coprophagy is also quite widespread in this animal group.

Some suctorial myriapods (all tetramerocerate pauropods and some millipedes), all with mouthparts more or less strongly reduced, are known to live on fungi or semiliquid end products of decaying plant material. Most pauropods feed on fungal hyphae and spores, but *Millitauropus* (Hexamerocera) feeds on small arthropods (springtails and their eggs). Symphylans are largely vegetarian, rarely saprophagous. Hence, the roles played by various myriapod groups in the terrestrial food chains differ, with millipedes being of particular importance as primary destructors and soil-formation factors and centipedes as active and restless predators. Representatives of only a few millipede orders are capable of manufacturing silk for cocoon production during molting or egg laying.

Reproduction

A few dozen cases of parthenogenesis are known (Enghoff, 1994). One is the lithobiomorph centipede *Lamyctes coeculus*, a synanthropic species known from several continents. Two small European millipedes (*Nemasoma varicorne* and *Polyxenus lagurus*), both mainly living under tree bark, exhibit geographical parthenogenesis, with bisexual populations in less disturbed areas and unisexual ones in areas where the species

appear to be recent colonizers. Similarly, *Poratia oblitterata* is bisexual in its native South American habitats, but more or less stable populations recently established in hothouse in Europe are parthenogenetic. There is also evidence of parthenogenesis in pauropods.

The life cycle of some tropical scolopendromorphs is annual, but in temperate regions a centipede life-cycle takes two or more years (Voigtländer, 2011).

All myriapods are oviparous. A lineage of centipedes (the Phylactometria, i.e., Craterostigmomorpha, Scolopendromorpha, and Geophilomorpha) have evolved brood care. In these animals, the female remains coiled (for as long as 3 months in some species) around her brood until hatching. Parental cares are virtually unknown in the other myriapod classes, with two of the rare exceptions being the millipedes *Polyzonium germanicum* (order Polyzoniida) and *Bericostenus humicola* (order Platydesmida), whose habits are comparable to those of the brood-caring centipedes. Egg brooding by the male has been recorded in a few species of platydesmidan millipedes.

A Diversity of Developmental Modes

Newborn millipedes have an incomplete number of segments and legs (Figure 4). In most cases, only three pairs of legs are present in the first active or inactive postembryonic stadium. New segments and leg pairs are added at each molt, sometimes inside constructed molting chambers, according to a precise schedule which is different in different orders, families, or genera. Three main developmental modes can be distinguished (Engelhoff *et al.*, 1994).

In hemianamorphosis (as in the pill millipede *Glomeris*) the final number of segments and leg pairs is obtained after some molts, but the millipede must undergo further molts without segmental increase before achieving adult size and sexual maturity. In teloanamorphosis (as in polydesmidans) the achievement of the final number of segments and leg pairs coincides with obtaining the adult condition and no further

molt occurs. In euanamorphosis (as in the cylindrical juliforms), new segments and leg pairs are added at every molt and the animal continues molting even after reaching sexual maturity.

The males of some western European representatives of the order Julida exhibit the peculiar developmental behavior known as periodomorphosis. Under specific adverse environmental conditions, sexually mature males of these species molt to intercalary males with regressed gonopods and suspended reproductive activity. After one or more additional molts, these animals reach a further mature stage, with newly differentiated gonopods.

Hemianamorphosis is also known in centipedes: Scutigermorphs, lithobiomorphs, and craterostigmomorphs hatch with 4, 7, and 12 pairs of legs, respectively, and obtain the final number of 15 leg pairs following one (craterostigmomorphs) or more molts but continue molting until they reach maturity. The remaining centipedes (scolopendromorphs and geophilomorphs), however, develop by epiamorphosis. That is, they reach the final number of body segments during the embryonic development; no segment or leg pair is thus added during the postembryonic life.

In symphylans, 6 or 7 of the final 11 or 12 pairs of legs are present in the first postembryonic stadium. Quite peculiar is the following developmental schedule in that first-order and second-order molts regularly alternate until maturity is reached. After each first-order molt a new two-segment unit is added, but only one more pair of legs is differentiated, whereas the second-order molts are accompanied by the differentiation of another pair of legs without addition of new segments. Mature symphylans continue to molt, up to 40 times in *S. immaculata*.

In pauropods, the first postembryonic stadium is a motionless pupoid with inarticulated traces of the antennae and of the first two pairs of legs. After a molt it changes into an active stadium with three pairs of legs. The development then proceeds by anamorphosis.

Number of Species Known and Expected

Our knowledge of myriapods is highly fragmentary and incomplete (Table 1). Not only does the bulk of existing species diversity remain to be described, but also the number of higher taxa appears to vary considerably as estimated by different taxonomists. In the Diplopoda, by far the largest of the myriapod classes, the situation concerning the number of orders and families, let alone genera and species, is badly equivocal to the point that Hoffman (1980) could equate the state of the art in millipede systematics to that in entomology in the middle of the nineteenth century. Thousands of taxa awaiting description are available in the collections. For example, according to Mesibov's online checklist, (<http://www.polydesmida.info/millipedesofaustralia/>), the collections of Australian millipedes already kept in Australia's natural history museums contain at least 1000 undescribed species, with only some 426 which have been named. Indeed, it is mostly tropical myriapod faunas that appear to be particularly rich but poorly explored.

Judging from the species described thus far, one millipede order outnumbers all others in terms of species counts –

Figure 4 The first postembryonic stages of a millipede (*Anadenobolus leucostigma martinicensis*; Spirobolida): (a) larva I with 3 pairs of legs; (b), larva II with 7 pairs of legs; (c) larva III with 21 pairs of legs (adapted from Nguyen Duy-Jacquemin M (1992) Contribution a l'étude du développement postembryonnaire d'*Anadenobolus leucostigma martinicensis* (Chamberlin 1918). Note préliminaire. *Berichte des naturhistorisch-medizinischen Vereins in Innsbruck* 10(supplement): 133–140.

Table 1 Myriapod diversity (approximate data), known and estimated

Class	Recent orders	Families	Genera	Species	
				Described	Estimated
Chilopoda	5	21	325	3300	6000–10,000
Diplopoda	15–16	130	1800	11,000	50,000–80,000
Paupoda	1	5	29	700	2000–5000
Symphyla	1	2	13	200	500

**Figure 5** Patterns of millipede generic diversity in Eurasia (reproduced from Golovatch SI (1997) On the main traits of millipede diversity in Eurasia (Diplopoda). *Senckenbergiana Biologica* 76: 101–106. 1, millipede-free territories; 2, 1–4 genera; 3, 5–10 genera; 4, 11–25 genera; 5, 26–50 genera; 6, over 50 genera. The data exclude obvious anthropochores.

Polydesmida (up to one-half of the genus and species richness of the Diplopoda), followed by Spirostreptida, Chordeumatida, and Julida. The remaining orders are minor to marginal. Thus, the pentazonian order Glomeridesmida contains only a single genus with a handful of species in the Indo-Australian and Neotropical realms. Similarly, the order Siphonocryptida is only represented by six species, one each in Macaronesia, Nepal, Taiwan and Sumatra, Indonesia, and further two in mainland Malaysia. The order Siphoniulida is extreme and obviously relict, being known by a single species each in Malaya and Central America.

Probably less than 20% of the world fauna has been described to date; this is particularly true of the largest class Diplopoda (Table 1). Indeed, updated counts/checklists are only available for the millipede faunas of some European countries (Kime and Golovatch, 2000). The fact that the numbers of genera and species of Diplopoda currently known in Europe and the Mediterranean are similar to those known from the whole of Asia shows how poorly investigated these are in the Asian, largely tropical fauna. An overview of the geographical distribution of millipedes, as a basis to reconstructing the history of their distribution on earth has been recently provided by Shelley and Golovatch (2011).

Detailed information on the geographical distribution of all centipede species is currently available in a website

(Minelli *et al.*, 2006; <http://chilobase.unipd.it>) and their world distribution has been recently discussed at the level of family and major geographical areas (Bonato *et al.*, 2009; Bonato and Zapparoli, 2011). A world list of Paupoda is available, but the distributional data concerning Symphyla are still scattered in the primary literature.

Geographical Patterns

The bulk of species richness is definitely confined to tropical countries, mainly woodlands, with certain notable exceptions. Thus, some orders or families appear to be largely temperate and more or less restricted to the Northern Hemisphere, e.g., Lithobiomorpha among Chilopoda or Glomerida, Julida, Callipodida, and Polydesmidae among Diplopoda. For these groups, the hot spots of diversity are mountainous lands at the periphery of the Holarctic Region within the temperate to subtropical areas such as the Atlas, Pyrenees, Alps, Balkans, Caucasus, Tien-Shan, Himalaya, and Appalachians. Figure 5 shows the patterns of millipede generic diversity in Eurasia.

Harsh environments such as tundra or deserts are populated by myriapods, patchily to marginally if at all, especially by Diplopoda (Golovatch and Kime, 2009) and Symphyla. However, Chilopoda, Paupoda, and even some Symphyla

occur in permafrost areas, and a few scolopendromorph centipedes are quite characteristic desert dwellers. In contrast, high-montane habitats, however adverse, are regularly populated by myriapods, inclusive of millipedes, and sometimes even by endemic species. The highest altitudes recorded are approximately 4500 m above sea level for millipedes. The highest record for centipedes is one of the *Lithobius* species at 5545 m asl in the Nepal Himalaya. In the Andes, species of *Lamyctes* have been recorded from up to 4400 m, whereas in Africa *Lamyctes emarginatus* occurs at 4000 m on Mt. Kenya and *Lamyctes africanus* at 4200 m on Mt. Ruwenzori.

Given the hundreds to thousands of species in each of the major myriapod groups, one may get the wrong impression that these basically cryptic animals should be highly diverse in most of the local environments, particularly in productive temperate or tropical forests. However, virtually no local fauna is known to include more than two or three dozen species, depending on habitat. Given that myriapods are basically composed of very ancient, widespread, but poorly vagile and largely stenotopic forms, most of the faunules, even among the richest and monotonous-like tropical rain forest, appear different at least to some degree (Golovatch and Kime, 2009). In other terms, ancient and widespread endemism is generally characteristic of Myriapoda.

Cold areas host a very reduced fauna of millipedes. In Europe, only two species (*Polyxenus lagurus* and *Proteroiulus fuscus*) live north of the Polar Circle; only two or no millipedes are known from such areas of Siberia or from Greenland, respectively (Golovatch and Kime, 2009).

Only relatively few nonanthropochoric species display vast distributions; these tend to be particularly large among predators (= Chilopoda), especially soil dwellers. Several geophilomorphs are examples of this pattern of distribution, e.g., *Arctogeophilus glacialis* and *Pachymerium ferrugineum*. Forms populating special but widespread habitats likewise appear widely distributed, e.g., the littoral geophilomorph *S. maritima* or the huge, largely arboricolous, neotropical scolopendromorph *S. gigantea*. Active colonizers of relatively young areas/habitats, such as the trans-Siberian *Angarozonium amurense*, the pan-European *Ommatoiulus sabulosus*, or the subcorticolous pan-European *P. fuscus* among millipedes or the Euro-Siberian *Lithobius curtipes* and some other congeners among lithobiomorph centipedes, reach up to the taiga and, in part, tundra belts in the north, the youngest boreal biomes. The Mediterranean chilopod *S. cingulata* is a notable colonizer of semiarid badlands, whereas the European symphylan *Symphylella vulgaris* is a colonizer of fresh mines.

Worldwide distribution due to human agency is known for several myriapod species, mainly of European origin such as the millipedes *Cylindroiulus latestriatus* and *Ophiulus pilosus* and the centipede *Lithobius forficatus*. The origin of the synanthropic centipede *L. emarginatus*, also widely distributed, is unknown but it is possibly from the Southern Hemisphere.

Endemism and Speciation

High numbers of endemic species and high percentages of endemics within the total millipede faunas are peculiar to

some environments such as caves and some areas, such as islands and some mountain chains in the temperate regions.

The best investigated cases of intense speciation in millipedes are by far those of the genera *Cylindroiulus*, *Dolichoiulus*, and *Acipes* in the Macaronesian area (Enghoff, 1992). On Madeira, of 60 millipede species known from the island, at least 29 belong to the endemic *Cylindroiulus madeirae* group (Julidae) and another 6 to an endemic lineage of the genus *Acipes* (Blaniulidae). Still more conspicuous is the *Dolichoiulus* (Julidae) species swarm in the Canary Islands, which has 46 species of a total of 79 millipede species thus far recorded from the archipelago. These *Dolichoiulus* species have colonized the most diverse habitats, from the laurisilva to the xeric habitats and the caves, whereas the Madeiran *Cylindroiulus* are all confined to laurisilva forest habitats.

In the Canarian *Dolichoiulus* species swarm, conventional allopatric (interisland) speciation is only marginally responsible for the genesis of the huge diversity of the group. According to Enghoff, speciation occurred mainly within individual islands, with distribution patterns governed mainly by habitat differences between closely related and nearly sympatric species. In several cases, those species which coexist in the same habitat differ conspicuously in size. The same is often seen in Madeiran *Cylindroiulus* and *Acipes* species; this rule, however, is far from universal.

Distribution by Continents

In general, the overall distribution of myriapods is quite consistent with the world's biogeographic regionalization known since the times of Hooker and Wallace. In other words, the traditional division of lands into the Holarctic (= Palearctic + Nearctic), Afrotropical (including Madagascar and the Cape), Neotropical, Oriental (Indian + Malesian), and Australian (including New Guinea and the islands of the southern Pacific) realms is supported by the patterns demonstrated by myriapod higher taxa. Antarctica is the only continent harboring no Myriapoda, whereas, due to the particularly poorly explored tropical faunas, the distribution of genera and species between the remaining continents or biogeographic regions is highly provisional and appears extremely uneven and patchy (Table 2).

The Diplopoda (Shelley and Golovatch, 2011) are indigenous to all continents except Antarctica and islands/archipelagos in all temperate and tropical seas and oceans except the Arctic; the group ranges from Kodiak Island and the northern Alaska Panhandle, US, southern Hudson Bay, Canada, and near or north of the Arctic Circle in Iceland, continental Scandinavia, and Siberia to southern Argentina, the southern tips of Africa and Tasmania, and Campbell Island, subantarctic New Zealand.

Glomerida, Platydesmida, Julida, and Callipodida occur exclusively in the Northern continents, whereas Glomeridesmida, Sphaerotheriida, Siphonophorida, Spirobolida, Epinannolenidea, Spirostreptidea, and Stemmiulida are primarily confined to the southern (Gondwanan) areas except for secondary dispersals in Mexico/Central America by all but Sphaerotheriida, which are absent from the New World. Siphoniulida and Siphonocryptida, known from only two and

Table 2 Distribution of centipede and millipede diversity among the major continents/regions^a

Class	Continent/region				
	Eurasia	North and Central America	Afrotropical region	Australia and South Pacific	South America
Chilopoda	1.3	1.5	0.5	0.5	1.1
Diplopoda	7.5	3.5	3.6	0.4	2.8

^aApproximate number of genera in hundreds.

four areas, respectively, are declining toward extinction. Polyxenida, Polyzoniida, Chordeumatida, and Polydesmida occur on nearly all continents, whereas Cambalidea inhabit North/Central America and southeast Asia with an isolated area in Iran.

Chilopoda are present almost worldwide, but there are no records from Antarctica, most parts of Greenland, the American and Asiatic arctic islands, and from a large part of western Saharan Africa (Bonato and Zapparoli, 2011).

Centipede diversity is highest in temperate and subtropical North America and in southern Europe; to a somewhat lesser extent also in southern Africa and in the Japanese archipelago. The Scutigermorpha have maximum diversity in southern and eastern Africa, the Indian peninsula, south-eastern Asia and Australia, the Lithobiomorpha in all temperate continental areas, the Scolopendromorpha in all tropical and subtropical regions, the Geophilomorpha in North America, most of South America, the Mediterranean basin, the southernmost part of Africa, the Japanese region, and south-eastern Asia. The only two species known of Craterostigmomorpha are restricted to Tasmania and New Zealand.

Hot Spots of Biodiversity and Endemism

The bulk of species richness is confined to the tropical countries, mainly woodlands (Golovatch, 1997), although there are some notable exceptions. The opposite extreme is represented by numerous species endemic, e.g., to a single cave or mountain slope; this is a special characteristic of Diplopoda. Local cavernicolous endemics, notably troglobites, are particularly numerous in southern Europe, especially in the Balkan area, which is rich in karst. The same actually concerns cave millipedes in most of the tropical countries. Similarly, nearly every patch of Amazonian primary rain forest near Manaus, Brazil, contains (much of) its own millipede faunule, with differences being particularly drastic between various kinds of inundation versus nonflooded (= terra firme) woodlands (Golovatch and Kime, 2009). Approximately the same pattern has been observed among Pauropoda.

The Fauna of Islands

Analysis of insular biotas clearly shows the differences in colonizing capability and radiation patterns of centipedes versus millipedes. In most faunas, the ratio of millipede to centipede species is approximately 4:1, but this ratio is much lower in Hawaii, Tahiti, Samoa, and the Fiji Islands. This reveals that centipedes are apparently better dispersers than millipedes. The distribution patterns of millipedes on continental versus oceanic islands are those of poor dispersers. For

instance, there are 18 millipede families represented by indigenous species in Sumatra, 17 in Japan, and 14 in Java, but there are only 10 in Australia, 9 in Madagascar, 5 in New Zealand, 3 in New Caledonia, and 1 in the Hawaii Islands. The number of endemic genera is very high in Indonesia and the Antilles, but these island groups do not have endemic families; suprageneric indigenous taxa are only known from Borneo.

The myriapod fauna of most of the oceanic islands is not simply disharmonic but also poor in species. Native myriapods are virtually absent from Kerguelen, Tristan da Cunha, and St. Helena.

Habitats and Adaptations

At least five morphological body plans and a few life-forms can be distinguished among millipedes (Golovatch and Kime, 2009). The pin-cushion millipedes (i.e., the representatives of the worldwide distributed order Polyxenida) are soft bodied, very small (usually <5 mm long), extremely bristly, swift, and capable of withstanding much drier conditions than most other Diplopoda. Many polyxenidans live under loose tree bark or are characteristic inhabitants of microcaverns and small crevices under stones, in the uppermost soil, in litter, and in similar substrates.

The pill millipedes (the largely Holarctic order Glomerida and the Afrotropical and Indo-Australian order Sphaerotheriida) are collectively termed “rollers” because of their ability to roll themselves into mostly glossy balls. Pill millipedes are generally litter dwellers, but some smaller Glomerida are either troglobionts or geobionts.

The colobognathans (i.e., the “sucking millipedes” with reduced mouthparts) and some Chordeumatida, which mostly possess flexible, worm-like, strongly tapered bodies, and shorter legs, are termed “borers.”

Many Polydesmida and numerous Chordeumatida, often conspicuously ornamented and relatively shorter, long-legged, and displaying more or less strong paranota (wing-like dorsolateral projections of the diplosegments), are referred to as “wedge types” and are characteristic of forest litter.

The lifestyle, or ecomorphological type, most common and widespread among Diplopoda is that of “bulldozers” or “rammers.” Their long, cylindrical, hard body with numerous diplosegments (hence, numerous pushing legs) penetrates the substrate like a bulldozer, using the broad head as a ram. Most juliform millipedes (Julida, Spirobolida, Spirostreptida, Calipodida, and some others) belong to this ecological type. This burrowing habit must have been critical in ensuring diplopods much or even most of their present-day high ecological and

geographical performance. In particular, unlike the remaining ecomorphotypes, only juliforms, among Diplopoda, appear to have colonized virtually any suitable habitat. In fact, in Juliformia belong the few littoral dwellers and deserticoles, but this body plan also provides most of millipede diversity in troglobionts and geobionts, in addition to anthropochores. Indeed, the northernmost record of a millipede belongs to the subcorticolous European species *Proteroiulus fuscus* (Julida) in the forest–tundra belt of Yamal Peninsula, Russia's north, whereas perhaps the most characteristic deserticole among millipedes is *Orthoporus ornatus* (Spirostreptida) in the southern US and adjacent parts of Mexico. Both these species are rare except in their native environments (Golovatch and Kime, 2009).

There are sound reasons to believe that, due to their capability to escape adverse conditions by burrowing in the soil, rotten logs, and similar shelters, juliforms (namely, species of the order Julida) dominate in Europe. This youngest, fully migratory nucleus of the millipede fauna, shows a clear-cut inclination to dwell on open terrain. In contrast, all the remaining millipede orders display very evident geographical trends in diversification. In Europe, even the relatively uniformly distributed Polydesmida have a remarkable center of secondary diversification in Slovenia, whereas the Chordeumatida are particularly species-rich within the Atlantic climatic zone of western Europe (Kime and Golovatch, 2000; Golovatch and Kime, 2009). Furthermore, only a few species of Julida, apparently in response to the strongly adverse conditions that existed in Europe during the Ice Age, appear to have developed a population strategy unique among terrestrial animals – the periodomorphosis strategy mentioned previously, i.e., the extension of male life by means of intercalary stadia.

In summary, most millipede lineages are currently in a phase of rapid evolution and speciation; however, there are a few apparently relict groups (Hoffman, 1980). Polydesmida seem remarkably diverse largely due to their wedge type of burrowing allowing ecological niche partitioning mainly in the litter and at the soil–litter interface. This is particularly obvious in tropical and subtropical faunas. However, examples of troglobionts, geobionts, and myrmecophilous as well as arboricolous species are about as numerous among Polydesmida as among juliforms, whose type of burrowing and lifestyle seem the most characteristic, widespread, and ecologically progressive among all recent Diplopoda.

Burrowing Myriapods

Several major myriapod groups tend to be soil dwellers. Usually, adaptations to geophily involve body elongation due to an increased number of segments. This is quite evident, for instance, in several lineages of geophilomorph centipedes, especially the Himantariidae and the Oryidae, which have a flexible worm-like body and peculiarly short appendages. This is also the case for certain scolopendromorph centipedes and some juliform and colobognathan millipedes, which are active burrowers. Body miniaturization also appears advantageous to dwelling in the crevices or burrows in the soil. This adaptation is observed in most Symphyla, numerous

Pauropoda, and some Diplopoda (e.g., some representatives of Glomerida, Julida, and Polydesmida). However, only more or less loose soils appear suitable for such myriapods because harder grounds are apparently too difficult to penetrate, especially by the actively burrowing species.

Open-Country Myriapods

Short-living Polydesmida are dominant in the savanna: The adults are active during the rainy season, whereas the juveniles spend the dry season in resting conditions. Resistance to desiccation varies much between species, with the females being mostly less sensitive than the males, for unknown reasons. Cuticular waxes seem to be present in very few millipede species. One of these species is *O. ornatus* of the American semideserts; when the temperature rises more than 40 °C, it rests in a coiled condition to reduce water loss. Lowest lethal temperatures for millipedes are in the range of –5 to –7 °C, and the highest temperatures are between 36 and 41 °C. Preferred temperatures are clearly lower for hygrophilous forest species (4–18 °C) than for xerophilous ones (e.g., 26–32 °C for *O. sabulosus*, a species common in open environments in southern and eastern Europe).

Special Habitat Myriapods

A few species have semiaquatic habits. One of them is the littoral julid *Thalassiosobates litoralis*, which can be found among the stranded decaying matters on the seashore. However, this species does not seem to spend much time under water, as do some cavernicolous species from southern Europe (several julids and the polydesmid *Serradium semiaquaticum*) and some Amazonian species, including *Myrmecodesmus adisi*, whose juveniles spend up to 11 months under water feeding on algae (Golovatch and Kime, 2009).

Both morphological and behavioral adaptations have been observed in myriapods that spend prolonged periods of time under water. Conspicuous are the microtrichia in their spiracles and the cerotegument covering their body which enable flood resistance for weeks and even months compared to the simple flood tolerance (up to a few days) exhibited by non-specialized forms. These morphological adaptations are present in a few millipedes of the seasonally inundated forests of Amazonia; they are also present in the polydesmid *S. semiaquaticum*, which inhabits caves near Verona (northern Italy), whereas its sister species *Serradium hirsutipes* does not have spiracular microtrichia and, as expected, does not have the flood resistance of its congener.

Regarding centipedes, resistance of seashore geophilomorphs to submersion in sea water is not very conspicuous, being 12–24 h in *S. maritima* and up to 36 h in *H. submarina*. Longer resistance to submersion in fresh water has been shown for the lithobiomorph *L. emarginatus* from European floodplains and from populations living along the Amazon River (personal communication from late colleague Adis).

Centipedes living in the floodplains must often face the problem of how to survive high water, basically choosing between running away and resisting somehow on the same spot. Several European lithobiomorphs, for example, *Lithobius microps*, *L. forficatus*, *Lithobius mutabilis*, and *Lithobius curtipes*,

are quite tolerant to inundation: Specimens of *L. curtipes* were found alive after 22 days inundation.

A few Amazonian species of Geophilomorpha show morpho-anatomical modifications in their respiratory opening (spiracles) for surviving submersion as adults; the henicopid lithobiomorph *Lamyctes adisi* has a dormant submerged egg stage; scolopendromorph and other geophilomorph centipedes climb up the trees to live there during the inundation period (Adis *et al.*, 1996; Morais *et al.*, 1997).

Behavioral adaptations to the seasonally flooded forest of Amazonia have also been recorded in the other myriapod groups. Regarding Symphyla, members of the Scolopendrellidae have a dormant stage of 5–7 months duration, which in the case of *Ribautiella amazonica* is spent among roots. Owing to the anoxic conditions of the flooded soil, these arthropods are likely to recur to anaerobic metabolism. A similar situation is presumed for Pauropoda living in the same environment because *Scleropauropus tarumamirimi* has been found to spend 5–7 months under water (Adis and Scheller, personal communication). Myriapods lacking similar morphological or physiological adaptations must rely on vertical migrations along the tree trunks to survive the flood period in the upper trunk or canopy region (e.g., *Cutervodesmus adisi* (Diplopoda), *Hanseniella arborea* (Symphyla), and some Geophilomorpha). The migratory behavior of these species, however, is the most conspicuous aspect of their complex ethological and physiological adaptations. No reproduction occurs during the time they spend on the trunks, and trunk ascent is associated with changes in local climatic conditions (“dry” vs. rainy season) and with macroclimatic influences such as the El Niño Southern Oscillation.

A large fraction of myriapods are represented by cave dwellers. Adaptations to life in caves are often opposite to those to geophily, frequently including larger sizes compared to their epigeic counterparts (Kime and Golovatch, 2000; Golovatch and Kime, 2009), often with strong paranota or hairs, elongated antennae and appendages, and reduced or missing ocelli. Among myriapods, troglobites are known mostly among millipedes and, to a lesser degree, centipedes. Many myriapods have developed adaptations to cave life and can be defined as trogllobites.

Regarding centipedes, approximately 50–60 trogllobitic species of lithobiomorphs and a few scolopendromorphs are known from caves of southern Europe: The Pyrenees, Sardinia, Italy, the Balkans, Greece, Turkey, Algeria, Morocco, Central America, and Australia. A trogllobitic geophilomorph (*Geophilus persephones*) has recently been described from the cave Gouffre de la Pierre Saint-Martin in the French Pyrenees; it is blind, as expected, but in this case the blindness is not a specific adaptation to cave life because all geophilomorphs lack eyes.

Modified mouthparts have evolved convergently in several unrelated genera of hygrophilous cave-dwelling millipedes from southern Europe and the Caucasus (Julidae: *Leucogeorgia*, *Typhloiulus*, and *Trogloiulus*; Blaniulidae: *Vasoblanulius*; Polydesmidae: *Serradium*). In these forms, the biting or masticatory part of the mandible is reduced, whereas its pectinate lamellae are hypertrophied, suggesting a function like a filter, used in collecting organic material suspended in water. Investigations on the gut content of *S. semiaquaticum*

from Italian caves, however, have failed to substantiate this expectation.

Parasitoids

HCJ Godfray, University of Oxford, UK

Introduction

A parasitoid is a type of animal that has a life history intermediate between that of a predator and prey. In general, parasitoids are invariably insects and their larvae feed at the expense of other insects, with the exception of a few species that attack different types of arthropods or mollusks. The adult female parasitoid lays her eggs on, in, or occasionally near the body of the host; the eggs hatch and the developing parasitoid larvae consume the host, eventually killing it. Like a parasite, only a single host is required for full development, but like a predator the host is invariably destroyed. The term parasitoid, originally coined by Reuter at the beginning of the twentieth century, is now used nearly universally to describe species with this life cycle, although in the older literature they are sometimes just called insect or protean parasites. Some solitary wasps have a similar life cycle except that the female parent carries paralyzed hosts to prepared nests or caches. Normally the requirement that hosts are attacked and oviposited on *in situ* is included in the definition of a parasitoid.

More than 50% of parasitoids belong to the insect order Hymenoptera: the sawflies, ants, bees, and wasps. The least-derived suborder is that of the sawflies (Symphyta), nearly all of which are phytophagous, although one family, the Orussidae, contains species whose larvae are parasitoids. From a lineage that was probably related to the Orussidae, the remainder of the Hymenoptera (the Aprocrita) evolved, and these are in turn divided into a huge group the Parasitica or parasitoid wasps, which are almost exclusively parasitoids, and the smaller Aculeata in which the ovipositor has become a sting. The Aculeata, derived from the Parasitica, are primitively parasitoids that have radiated into a wide range of feeding habitats, including predators, scavengers, and pollen feeders. The Aculeata contain nearly all the Hymenoptera familiar to the general public, including all the species of ants, bees, and wasps that show advanced sociality (eusociality). The Parasitica are classified into a large number of families and superfamilies, the most important of which are the Ichneumonidae, Braconidae, and Chalcidoidea.

The second major group of parasitoids belongs to the two-winged flies or Diptera. The parasitoid habit has evolved on many occasions in this order, with the most important taxon being the family Tachinidae: these are almost exclusively parasitoids, with the adults frequently resembling houseflies (Muscidae, like the Tachinidae in the Calypterata). The parasitoid habit has also evolved on many occasions in the beetles (Coleoptera), although a relative small number of species feed in this way. The most frequently encountered beetle parasitoids are probably those in the rove beetle family (Staphylinidae). Outside the three insect orders just mentioned, parasitoids are extremely scarce and taxonomically scattered.

As described in more detail later, parasitoids are important members of nearly all terrestrial ecosystems, but there is little agreement about how many species exist. Currently, about 10% of the approximately 1 million described insects are parasitoids, but parasitoids are almost certainly less known compared with other groups—parasitoid taxonomy is legendarily difficult. Most workers today would argue that there are between 4 and 8 million species of insects on Earth, of which 1.5–2 million are parasitoids. To put this into perspective, recall that there are less than 10,000 species of birds and approximately 5000 species of mammals.

Life History Variation

A simple way to classify parasitoids is by the host stage that they attack. Holometabolous insects have three juvenile stages (egg, larva, and pupa), whereas hemimetabolous insects have nymphal stages with no pupal metamorphosis. The most common category of parasitoids is composed of those that attack larval or nymphal stages, although egg and pupal parasitoids are also common. The least common type is adult parasitoids, probably because the adult is best able to defend itself against parasitoid attack. Egg parasitoids deposit their own eggs within that of their host and are obviously very small insects. This life history has evolved several times but is most common in two families of chalcidoid wasp: the Trichogrammatidae and the Mymaridae. Members of the latter family, which have very narrow wings with pronounced cilia (fine hairs) and are known as fairy flies, include the smallest of all known insects. Some parasitoids oviposit into the eggs of their host, but their larvae only kill the host later when it is a larva or pupa. These are called egg–larval or egg–pupal parasitoids, whereas another common life history is found in larval–pupal parasitoids.

Most parasitoid eggs are deposited in or on the host, but a substantial minority (especially among the flies and beetles) is deposited in the vicinity of the hosts, and the final stages of host location are carried out by a specialized first-instar larva (a triangulum or planidial larva). There are two main modes of parasitoid larval development: as endoparasitoids or as ectoparasitoids. As their names suggest, the former feeds internally within the host and the latter externally. Occasionally, a parasitoid species may begin life as an ectoparasitoid and switch midway through development to an endoparasitoid or vice versa. Ectoparasitism is found most frequently in species that attack concealed hosts in plant tissue or other refuges, where the external feeding parasitoid has some protection from the environment and predators. Parasitoids can also be classified as idiobionts or koinobionts. Idiobionts kill or permanently paralyze their host at oviposition, whereas

koinobionts either do not or only temporarily paralyze the host so that it recovers and continues feeding. The parasitoid suspends its own development, normally as a first instar, and waits for the host to reach a size at which it can support its development, whereupon it resumes growth that results in host death. The koinobiont life history, normally found only in endoparasitoids, allows the adult parasitoid to attack hosts when they are still too small to support the full development of the progeny. However, while in a state of suspended development, the parasitoid larva is at risk from the host insect's immune system.

Part of the definition of a parasitoid is that its larva requires just a single host for development; however, it is possible for several parasitoids to share the same host. Species in which only a single parasitoid develops per host are termed solitary as opposed to gregarious parasitoids. The larvae of solitary parasitoids tend to have large mandibles which they use to attack other parasitoids in the host, whether conspecific or of a different species, and thus the difference between the two types of parasitoids is more than just one of degree. Occasionally, very large numbers of parasitoids emerge from a single host, for example, several hundred braconid wasps from a single hornworm (hawkmoth, Sphingidae) larva, although the largest broods are known to be associated with certain specialized wasps with polyembryonic development. In these species (particularly in certain genera of chalcidoid Encyrtidae), one or two eggs are laid into the host, but these divide asexually to produce many embryos—occasionally, hundreds and sometimes more than a thousand.

Unlike predation, in which feeding removes a prey item, a parasitized host may be discovered by a second parasitoid individual prior to its destruction. Sometimes, parasitoids avoid previously parasitized hosts, a practice called host discrimination, and this may be aided by chemical marks deposited by the first female. However, in many circumstances the second female will be selected to add its own eggs to the host. If the second individual is of the same species as that of the first, this is termed superparasitism, whereas if it is of a different species the term multiparasitism is used. Occasionally, a female may parasitize a host that she had previously attacked (self-superparasitism). Some, but not all, parasitoid species can distinguish between hosts previously parasitized by self and by other conspecifics. In superparasitism and multiparasitism, the parasitoid larvae compete with each other for host resources; when hyperparasitism occurs, one parasitoid larva actually feeds on the other. There are two main categories of hyperparasitism: obligate and facultative. As the name suggests, an obligate species can only develop as a parasitoid of a parasitoid, whereas a facultative species develops as a normal parasitoid when it encounters an unparasitized host and as a hyperparasitoid when it discovers a previously attacked host. Hyperparasitism is sometimes called secondary parasitism (as opposed to primary parasitism) and cases of tertiary and even facultative quaternary parasitism have been recorded. An unusual life history is found in some chalcidoid wasps of the family Aphelinidae: females develop as primary parasitoids, but males develop as secondary parasitoids of other aphelinids (including females of the same species).

Host Location

Parasitoids are small to tiny animals that search for hosts that are themselves small or tiny animals in a very complex environment. They have solved the formidable problems of host location by making use of a battery of clues and stimuli that reveal information about the presence or potential presence of hosts. The majority of these cues, especially those acting over long ranges, are chemical, but visual, tactile, thermal, and auditory information is also used. Moreover, the parasitoid is not a hard-wired automaton but constantly updates its estimates of the values of different stimuli to modulate its strategies for host location.

One can envisage a parasitoid as utilizing a hierarchy of stimuli with increasing information content. Perhaps the lowest-grade stimuli point to habitats or microhabitats that might contain hosts. Many parasitoids attacking plant-feeding hosts orientate toward green objects, whereas the parasitoids of *Drosophila* that feed on different types of fermenting substrates are attracted to volatile chemicals characteristic of their hosts' microhabitat. Plants damaged by herbivores release a cocktail of volatiles, which are often highly attractive to parasitoids. In some cases, parasitoids respond to artificially damaged hosts, whereas in other cases they are only attracted to the "host–host plant" complex. It has been shown that the plant's response to particular herbivores and their salivary and other secretions can be very specific, prompting the intriguing suggestion that the plant may have been selected to recruit "bodyguards" to protect itself against its herbivores.

Host waste products reveal valuable information about their originator's whereabouts. Many parasitoids are highly attracted to host frass (feces), while volatiles associated with salivary or mandibular gland secretions, or with silk, are also used in host location. Some hosts have symbiotic relationships with other organisms that may provide clues to their location: for example, wood-boring sawflies are associated with symbiotic fungi that digest the wood, and their parasitoids are strongly attracted to chemicals released by the fungi.

Clearly, hosts will be under strong pressure to reveal as little about their location as possible to searching parasitoids. Many parasitoids use vision in host location and camouflage and immobility may help protect hosts against parasitoids and more traditional predators. Vibration is particularly important for species attacking hosts feeding on concealed material, and some hosts "freeze" if they detect the presence of a searching parasitoid. There is evidence that parasitoids may also use thermal gradients to detect the presence of concealed hosts.

Hosts should maintain as far as possible the chemical equivalent of "radio silence," although sometimes hosts have to advertise themselves for different reasons and in doing so may provide clues to searching parasitoids. Some bark beetles (Scolytidae) can only overcome tree defenses by mass attacks of many hundreds or thousands of individuals, and these are coordinated by the beetles releasing an aggregation pheromone. However, not only other beetles but also their larval parasitoids are attracted to the pheromone. Similarly parasitoids may be sensitive to their host's sex pheromone. This is useful both for species that attack the adult host and those that use the presence of the adult as a cue for finding other life history stages. A particularly devilish instance of parasitoids

subverting their hosts' sexual signaling is that of the dipteran parasitoids of grasshoppers that home in on stridulating males.

Parasitoids are born with an innate hierarchy of responses to different stimuli, but they will change the position of cues in this hierarchy and incorporate new stimuli as they gain experience in host location. For example, if a novel volatile chemical such as vanilla is presented to the parasitoid at oviposition, the parasitoid learns to associate this chemical with hosts and subsequently flies to baits releasing this chemical. In a more natural setting, *Drosophila* parasitoids preferentially fly toward certain potential host microhabitats if they have previously been successful in finding hosts in that microhabitat. Many parasitoids, as they emerge from their pupa or cocoon, carefully examine with their antennae any remains of the host at the pupation site. They appear to be learning potential host cues because they subsequently fly toward sites containing the same volatile chemicals. An interesting corollary to this behavior is that it will tend to promote the formation of host races or biotypes.

Hosts are often found in patches that parasitoids exploit, but with decreasing returns as the fraction of unparasitized hosts declines. There will thus come a time when the parasitoid will be selected to abandon the current patch and search for a new site. Studying parasitoid patch use behavior has many parallels with predators searching for prey that are distributed in patches. This is one of the classical problems of optimal foraging theory, a field of behavioral ecology. In the simplest case, predators should leave the patch when their instantaneous rate of gain of food equals the maximum long-term rate that can be achieved in that environment. Longer patch residence is thus predicted in poorer environment, for example, when interpatch travel times are long.

The qualitative predictions of patch use theory have been supported by studies of parasitoids, but specific aspects of their searching behavior complicate the theory's application. For example, previously parasitized hosts do not disappear (as do eaten prey) but remain as potential sites for superparasitism. The parasitoid may also have to waste time in identifying them as parasitized, although they may provide useful information about host distributions. Parasitoid behavior may also change critically in the presence of conspecifics: when a parasitoid is searching a patch alone, any superparasitism is normally damaging self-superparasitism, which is not the case if other females are active at the site. Current research in this area using statistical models based on survival analysis seeks to identify the precise factors that determine when a parasitoid abandons the patch.

Host Acceptance and Oviposition Strategy

After a parasitoid locates a host, it then has to make a series of decisions that are very important for its future reproductive success. First, it must decide whether the host is of sufficient quality to be used as an oviposition site, or whether to search for a better host, perhaps using the current host as food, so as not to waste eggs. Given that the host is of sufficiently good quality, gregarious parasitoids have to decide how many eggs to lay, while hymenopterous parasitoids have to decide whether to lay male or female eggs. Only Hymenoptera have to

make this last decision because they have a genetic system called haplodiploidy in which females develop from fertilized eggs and males from unfertilized eggs. By choosing whether or not to fertilize the egg, the parent can control the sex of its offspring. Unlike groups in which sex is determined by the random segregation of sex chromosomes, natural selection can operate on the behavior of haplodiploid females to produce sex ratios adapted to local conditions.

Before laying an egg, most parasitoids determine whether a potential host is suitable by examining it externally, and in the case of endoparasitoids often internally as well by using sensillae on their ovipositors. In either case, a host may be rejected if unsuitable, perhaps because it is of the wrong species. As part of biological control campaigns, parasitoids sometimes have to be mass reared, and much effort has gone into investigating whether they can be reared on artificial hosts. Critical to a successful strategy of this type is an understanding of exactly what host stimuli trigger oviposition.

Even if a host can potentially support a parasitoid larva, it may still not be worth laying an egg if the resulting offspring is of poor quality, perhaps very small in size. Understanding how natural selection molds host acceptance behaviors has many parallels with understanding how natural selection influences diet breadth in predators and other consumers, a second major strand of optimal foraging theory. Theory assumes that predators should maximize their rate of gain of energy (or other resources) and hence should not take "time out" from searching for good-quality prey items to attack poorer-quality types as the energy returns from the latter do not justify the time it takes to subdue and process them. Applying these ideas to parasitoids, searching females should not waste time ovipositing on poor-quality hosts when that time could be better spent searching for good hosts. Exactly what constitutes a poor host thus depends on the quality of the environment: attacking a particular host of medium quality might be economically advantageous in a habitat in which very good hosts are rare or absent, but it may not make sense in an environment in which the best hosts are abundant. There is experimental support for this prediction.

In many cases, the simple assumption that parasitoids should seek to maximize their rate of gain of reproductive success with time is probably overly simplistic. All parasitoids have a limited number of eggs, and maximizing the rate of gain of fitness may lead to the exhaustion of egg reserves prior to death. More sophisticated models have been developed that maximize reproductive success over the lifetime of the insect and predict that the parasitoid may become more selective as its egg supply diminishes. Again, there is experimental data supporting this prediction, although whether egg limitation is a major feature of parasitoid biology is a highly contentious topic. Another factor that may influence oviposition decisions is host feeding. Many adult parasitoids can feed from hosts, although this normally results in the host's destruction. Host feeding provides the parasitoid with energy and nutrients and hence allows it to produce more eggs. Thus, there is a trade-off: should the parasitoid use a host for reproduction and possibly risk later starvation or egg exhaustion, or should it forgo an immediate increment in fitness in the hope of deferred pay-back? In these circumstances, it clearly makes sense to feed from suboptimal hosts.

The question of optimal clutch size in parasitoids can be explored using similar economic arguments. In this case, the ideas originally developed to understand how natural selection operates on bird clutch size. An obvious prediction is that parasitoids should adjust their clutch size to the amount of resources available, and there is ample evidence that parasitoids do this, with the numbers of eggs laid typically being closely correlated to the size of the host. Careful experiments have shown that parasitoids can often estimate host size from very subtle cues; for example, some egg parasitoids can assess host size by very limited information about the local curvature of the host egg. As eggs are added to the host, the fitness returns from each egg typically decline because the members of the brood compete with each other for a fixed pot of resources. The optimal clutch size is defined as the number of eggs for which the marginal returns from adding additional eggs exactly equal the marginal opportunity costs in terms of wasted time or wasted eggs on the current host. This argument suggests that in good-quality environments in which fresh hosts are easy to discover, smaller clutches should be laid. Similarly, small clutches should be found in circumstances in which egg reserves are low. Experiments on gregarious parasitoids have supported both predictions.

Are solitary and gregarious parasitoids just part of a single continuum in clutch-size behavior? There are arguments that suggest this is not so: solitary parasitoids typically have large mandibles which they use to attack any other parasitoids in the host, including siblings, whereas gregarious parasitoids do not have this aggressive behavior. For evolution to convert a solitary parasitoid to a gregarious parasitoid, natural selection must operate not only on parental clutch size behavior but also on larval morphology and fighting. Although adult parasitoids and their offspring have many evolutionary interests in common, these interests are not identical and there is the potential for evolutionary parent-offspring conflict. Models incorporating this genetic conflict predict that the solitary life history is qualitatively distinct from gregariousness, and that there is hysteresis in the transition between the two states with gregariousness being far more difficult to evolve from the solitary state than vice versa.

The study of the sex ratio is one of the most successful areas of evolutionary ecology. The problem is to predict why some species of plants and animals produce sex ratios that differ from the 50:50 ratio. For a deviation to occur, there must not only be the selection of a biased sex ratio but also the flexibility to control son and daughter ratios. Haplodiploid parasitoid wasps have been critical in developing this field because they have both the incentive and the means to produce unusual sex ratios.

As Fisher demonstrated in the 1930s, a 50:50 sex ratio is expected to evolve because were the population to be biased toward females, sons would be a more efficient way of getting genes into future generations (because they would, on average, mate with more than one female), whereas if the population were to be biased toward males, daughters would be a more efficient way of getting genes into future generations (because sons would mate, on average, with less than one female). However, this argument assumes that the population is completely mixed and that all males compete for all females. This assumption breaks down if sons compete for mates, including

their sisters. In such situations, the ovipositing female is selected to produce fewer sons to avoid wasteful within-family conflict and also to provide more potential mates for the male offspring. Hamilton, who in the late 1960s developed these ideas, called this process as local mate competition and marshaled a long list of examples in which mating among siblings was associated with female-biased sex ratios: 18 of the 26 examples he quoted were parasitoids.

Recent studies have shown that some parasitoids are able to assess the degree of local mate competition that their progeny is likely to experience and to adjust their sex ratios accordingly. For example, *Nasonia vitripennis* is a gregarious parasitoid of fly pupae (e.g., of blowflies that live in birds' nests). Wasps emerge in the bird's nest and mate prior to dispersal (the male has limited powers of flight). If a single female colonizes a bird's nest, all her offspring will mate among themselves and the wasp should produce just enough sons to mate all her daughters; if two females colonize a nest then local mate competition still occurs, although it is less intense, and a sex ratio of approximately 25% males is predicted. With greater numbers of females, the sex ratio quickly asymptotes at 50%. In laboratory experiments in which the number of insects searching together is manipulated, females respond to the presence of conspecifics by producing less female-biased sex ratios.

It had long been noted that parasitoid wasps often lay male eggs in small hosts and female eggs in large hosts, but why this evolved was only understood in the late 1970s by Charnov as part of a wider theory of environmentally correlated sex ratios. In parasitoids, there is normally a strong correlation between host size and the size of the adult wasp that eventually emerges from it. In general, wasps suffer from being small; they tend to have reduced longevity and fecundity and are less able to withstand the insults thrown at them by the environment. However, the negative consequences of being small are probably not experienced equally by the two sexes. In particular, female reproductive success may depend more critically on size than does male reproductive success for the simple reason that eggs are expensive and sperm cheap. This assumption is difficult to test because it requires size-dependent fitness to be measured in the field, which is difficult for such small animals, but the limited amount of available evidence supports this notion. If female fitness increases more rapidly with size than does male fitness, then Charnov's theory predicts that males should be laid in relatively small hosts and females in relatively large hosts. Moreover, there should be a sharp threshold in host size below which only males, and above which only females, are produced.

Laboratory experiments tend to show a threshold in host size as predicted by theory, although typically it is not as sharp as expected, perhaps because the wasp is using subtly different cues to assess host size from those used by the experimenter. To test whether relative or absolute size is important, many workers have presented medium-sized hosts to wasps in conjunction with either larger or smaller hosts. Theory predicts that the wasp should produce male eggs in medium-sized hosts when they are relatively small and female eggs when relatively large. Some wasps do indeed do this, although others have a much more fixed behavior, responding only to absolute host size. Possibly, these wasps always encounter the

same host distribution in the field and hence have never evolved the flexibility to deal with variable patterns of host size.

Resistance and Virulence

Endoparasitoids that delay their development while the host continues to feed and grow in size have to protect themselves from the host's defenses. The main host defense against parasitism is a cellular immune response called encapsulation. Cells (hemocytes) circulating in the blood cavity (hemocoel) recognize a parasitoid egg or larva as foreign and cause other cells to aggregate against the intruder, forming a capsule. The cells in the capsule fuse, and the whole structure becomes hardened and melanized, thus leading to the death of the parasitoid either through suffocation or through the release of necrotizing substances by the parasitoid. Encapsulation is not a specific antiparasitoid measure but rather operates against any foreign body.

There are two broad parasitoid strategies to counter host resistance: passive and active defense. In the first case, parasitoids either camouflage themselves so that they are not recognized as foreign or insert their eggs in specific organs away from circulating hemocytes. How this camouflage works can be seen in some species in which the egg is coated with a layer of protein prior to injection into the host. If the egg is dissected out of the wasp and the protein layer removed, the egg becomes susceptible to encapsulation if artificially "oviposited" into the host. Many parasitoids carefully position their eggs in the host brain or ganglia where they avoid hemocytes, while even eggs placed in the hemocoel may obtain some protection by sticking to fat body and other host organs.

The most common form of active defense is the injection of toxins at oviposition or their later secretion by the developing larva. It is common for the ovipositing female to temporarily paralyze the host so that it is easier to handle, but the same or other substances can also damage the host's immune system. Many parasitoids, though so far only Hymenoptera (particularly the Ichneumonoidea), inject viruses into the host at oviposition. The best-studied type is polydnavirus, so named (poly-DNA-virus) because the genetic material is composed of many separate DNA molecules within a single protein coat. The viral DNA is stably integrated within the wasp's genome, but in certain cells of the female reproductive tract it is copied, greatly amplified, and encapsidated. In the host, the virus does not replicate, but it does invade the hemocytes responsible for encapsulation which it can destroy by triggering apoptosis. How polydnaviruses evolved is not clear: in particular, are they part of the wasp's genome that has acquired virus-like properties or are they originally autonomous viruses that have been captured and tamed by the wasp? Instances are known of wasps injecting viruses that appear unrelated to polydnaviruses and also of wasps injecting virus-like particles that resemble the protein coats of viruses but contain no DNA.

Parasitoid eggs are surrounded by embryonic membranes which normally disintegrate after hatching. However, in some species, the cells of the membranes dissociate and float free in

the hemocoel where they grow enormously in size. These cells are called teratocytes, and their primary role is most likely secretory (they are packed full of endoplasmic reticulum), producing substances that limit the host's immune defense. When the parasitoid is fully grown it consumes the teratocytes, which may thus also have a nutritive function.

Hosts and parasitoids almost certainly exert very strong selection pressures on each other, and observed levels of resistance and virulence will be determined by this coevolutionary interaction. Two major factors determining the outcome are the asymmetry in the interaction and the nature of the costs of resistance and virulence. The interaction is asymmetric in that every parasitoid has to overcome its host's defenses to survive, whereas not every host is parasitized. Models of the dynamics of host-parasitoid coevolution predict that in certain circumstances hosts may be selected not to defend themselves but to "gamble" on not being attacked. A major determinant of whether this strategy is favored is the nature of the costs to the host of investing in resistance mechanisms and to the parasitoid in investing in counter-measures. Costs are difficult to measure, but artificial selection experiments in the fruit fly, *Drosophila*, have shown that increased resistance to its parasitoids is accompanied by a decrease in competitive ability under conditions of resource stress. It appears that the fly switches limiting resources from optimizing feeding efficiency to immune function.

Associations with Microorganisms

The last 10 years have seen an enormous growth in our knowledge about associations between insects and microorganisms, particularly bacteria. This research programme has revealed a variety of interactions between parasitoids and microorganisms that are affecting our understanding of numerous aspects of their biology.

We now know that many types of bacteria are associated with insects and are transmitted vertically to their offspring, typically with some horizontal transmission occurring, though much more rarely. In order for a bacterium that is always, or nearly always, transmitted vertically to spread and maintain itself it must either increase the fitness of its host, or in some way manipulate its host's reproduction such that more daughters are produced by infected compared to uninfected females. It is this latter route that many symbiotic bacteria of parasitoids have taken.

The most common bacterial associate of parasitoids is *Wolbachia*, which is found in numerous species as well as in many nonparasitoids. The dominant means by which *Wolbachia* spreads is through cytoplasmic incompatibility. In a way not yet fully understood *Wolbachia* in males modifies the sperms such that they can only be used by infected females. Because uninfected females can only mate successfully with uninfected males while infected females can mate successfully with everyone, the latter have an advantage (at least when the infection is above a threshold density). Work on *Wolbachia* in parasitoids established much of the biology of the bacterium, as well as some of its possible consequences for population differentiation and speciation. Typically, researchers use antibiotics to "cure" species of *Wolbachia*, and then observe how

this affects mate use. Curiously, in *Asobara*, a species that attacks *Drosophila*, removing the *Wolbachia* leaves the wasp unable to reproduce. Recently, a second bacterium that also spreads through cytoplasmic incompatibility, *Cardinium*, has also been discovered in a parasitoid wasp.

Because parasitoid wasps have a haplodiploid genetic system in which males develop from unfertilized eggs, it is probably easier, compared with other organisms, for bacteria to spread by causing its host to reproduce parthenogenetically. This strategy has been adopted by a number of *Wolbachia* strains infecting different parasitoid species, especially the egg parasitoid *Trichogramma*. These findings validate several observations in the old biological control literature that heat shock could cause parthenogenetic species to produce the occasional male: the heat shock temporarily incapacitates the bacteria. Typically, curing the wasp of *Wolbachia* restores male production though in some, presumably very old associations, the ability to produce males seems to have been lost.

Finally, some bacteria spread by “male-killing”; destroying sons so that daughters benefit by having more resources. In parasitoids this was first observed in the gregarious wasp *Nasonia*, which oviposits a mixture of male and female eggs into a fly pupa. A bacterium called *Asenophonus nasoniae* causes the death of males leading to bigger and fitter females because they do not have to compete with their brothers. Spread through male-killing requires interactions among broods, and this is surprisingly widespread in insects with gregarious larvae.

As noted above, not only parasitoids but many other insects have symbiotic bacteria, and phylogenetic studies suggest that horizontal transfer must occur, if only occasionally. Frequently, the mode of horizontal transfer is a mystery, particularly as most bacteria are obligate intracellular parasites. It has often been suggested that parasitoids may vector bacteria between species, or may contract bacteria from their host, and there is some phylogenetic evidence for this in species infected by *Wolbachia*.

Lastly, symbiotic bacteria may also spread by providing benefits for their host. Virtually all aphids possess a primary symbiont that provides essential nutrients missing from its phloem diet. But many clones possess secondary, nonobligate symbionts. Recently, it has been shown that two facultative symbiont bacteria increase aphid resistance to parasitoids, although how they do so is not yet known.

Population Dynamics

The study of host–parasitoid population dynamics has received considerable attention for two main reasons. First, parasitoids are important biological control agents and understanding how they may regulate their host has clear applied relevance. Second, host–parasitoid interactions are a useful model system for answering broader questions in population biology applicable to all resource–consumer interactions. Host–parasitoid interactions are attractive as model systems because of the simplicity of the trophic relationship: in most cases, a parasitoid attack results in one (solitary species) or a certain number (gregarious species) of recruits to the next generation of parasitoids. This is in contrast with predation, in which it is far more difficult to

predict how a single instance of prey capture influences the future number of predators.

Modern consideration of host–parasitoid population dynamics began in the 1930s, particularly through the work of the Australian ecologist Nicholson and his collaboration with the mathematician Bailey. They considered the case of a host–parasitoid interaction with discrete, synchronized generations. Hosts are exposed to parasitoids during a fixed developmental stage, and those that survive parasitism and other sources of mortality produce the next generation of hosts the following years. Parasitized hosts are the source of the subsequent parasitoid generations. In their basic formulation, known as the Nicholson–Bailey model, they assumed that parasitoids searched randomly in the environment. The average number of times a host is encountered is then simply a product of parasitoid density (P) and a constant (a) known as the attack coefficient. Provided that the parasitoid search is random, the probability of escaping parasitism is simply the zero term of a Poisson distribution with this mean (i.e., e^{-aP}).

The Nicholson–Bailey model is important because it encapsulates the minimum bare bones of a host–parasitoid interaction. It tells us what to expect in the absence of any biological complications, and what it tells us is perhaps surprising. If the Nicholson–Bailey model is iterated over many generations, the densities of hosts and parasitoids oscillate with ever-increasing amplitude until one or both species go extinct. In essence, the parasitoid overexploits the host, which crashes to low densities, and this is followed by a drastic decline in the parasitoid number. The host then recovers and in the temporary absence of the parasitoid increases to higher densities than before; this is followed, after a lag, by a huge growth in parasitoid numbers and even more cataclysmic overexploitation. The combination of random search and the time lags inherent in this discrete-generation framework does not allow a host–parasitoid interaction to persist.

The intrinsic instability of the Nicholson–Bailey framework has set the agenda for much of host–parasitoid population dynamics in the past 60 years: what aspects of real host–parasitoid interactions allow the persistence that is so palpably clear in the field? Introducing a realistic functional response (a limit on the number of hosts a parasitoid can attack due to egg or time limitation) does not help, and if anything, it makes nonpersistence more likely. In the 1960s and 1970s, many workers thought that interference between parasitoids was the key. Interference is said to occur if female parasitoids disrupt each other’s searching, perhaps because when two parasitoids meet they fight or in other ways interact. Such interference might reduce the efficiency of high-density parasitoid populations and break the cycle of overexploitation and recovery. However, although interference occurs and can be measured in the laboratory, a consensus soon formed that in the field it was unlikely to be strong enough to allow persistence. Another idea was to assume that in addition to parasitism, hosts were also subject to direct density dependence due to competition for food. This additional density dependence can stabilize the Nicholson–Bailey interaction and may very well be important in some host–parasitoid interactions in the field. However, it is unlikely to be the complete answer because at the stable population densities that are predicted by this model, there is still substantial

competition for food. This theory can neither explain why so many hosts are regulated at levels well below their food-carrying capacity nor why parasitoids can cause such dramatic reductions in host density after their release in biological control programs.

Most workers today believe that host–parasitoid persistence involves a general phenomenon called heterogeneity of risk (this idea actually dates back to the last papers of Nicholson and Bailey in the 1960s). Overexploitation of the host population occurs because all hosts are equally susceptible to parasitoid attack, and therefore nearly everyone succumbs when parasitoid densities are high. However, suppose that some hosts are in a refuge and protected from parasitoids. These individuals can survive periods of high parasitoid densities and prevent the crash in host density that initiates the diverging oscillations (of course, if too many hosts are in a refuge then the parasitoid will not be able to prevent the host population from increasing without restraint).

What might these refuges be? There are many possibilities. First, there may be physical refuges in which hosts are protected from parasitism. For example, the host might be a stem borer and a certain fraction of hosts may burrow so deeply in the plant tissues that they are inaccessible to parasitoids. Second, a certain fraction of the hosts may be physiologically immune to parasitoid attack. Third, there may be a phenological mismatch between host and parasitoid: some hosts may avoid parasitoids by emerging either sufficiently early or late in the season so that they miss all or most searching parasitoids.

Finally, and probably the most important, the refuge may not be physical, physiological, or phenological but statistical: a certain number of hosts, more than would occur if the parasitoid search was random, may escape parasitism by chance each year. For example, let us suppose that hosts are distributed across the environment in patches, and that certain patches are more attractive than others to parasitoids (for reasons not associated with host densities, some patches may be in areas that are more likely to be encountered by parasitoids). Provided enough hosts occur in rarely encountered patches—statistical refuges—the interaction will be stable. (A popular way to model this is to replace the Poisson distribution in the Nicholson–Bailey model with a different, more aggregated statistical distribution such as the negative binomial. The resulting interaction is stable provided the variance of the distribution is sufficiently large.) All these ways of stabilizing the Nicholson–Bailey model rely on there being differences among individuals in the risk of parasitism; hence their general labeling as models of heterogeneity of risk.

Recent developments in host–parasitoid population dynamics have largely involved the study of interactions with overlapping rather than discrete, synchronized generations and interactions in which the spatial distribution of the population needs to be taken into account. Models for species with overlapping generations typically abandon the discrete time difference equations of the Nicholson–Bailey model and use instead differential equations, although they often incorporate time delays to represent developmental lags. Two new insights have come from this approach. First, an interaction that is otherwise identical to the Nicholson–Bailey model may be persistent if there is a long-lived, invulnerable host stage. The reason for this relates to the arguments regarding the heterogeneity of risk

discussed previously: the long-lived invulnerable stage provides a refuge that allows the host population to ride out periods of very high parasitoid densities.

The second insight to emerge concerns when hosts and parasitoids differ in generation time, in particular, when the parasitoid generation time is approximately half that of the host. The population can then display persistent cycles with a period approximately equal to the host generation time. This is of more than technical interest because such cycles are common among pests of tropical plantation trees such as coconut, oil palm, and cocoa, and these pests tend to be attacked by parasitoids with shorter generation times. The cycles arise because of dynamic interference between the two time lags in the system. Suppose there is a temporary increase in the densities of host: the progeny of this “blip” will form a secondary blip one host generation later. However, the parasitoids will also be able to take advantage of the increase in host population density, and this will result in a secondary increase in their densities one parasitoid generation later. If the two generation times are equal, the two secondary blips coincide (the Nicholson–Bailey situation), but if the parasitoid generation time is approximately half that of the host the two blips do not coincide, and the parasitoid causes a trough in host density, an “antiblip,” half a host generation later.

There are two main ways to incorporate a spatial component into host–parasitoid models. The first is to assume that the system consists of discrete subsystems linked by migration, whereas the second is explicitly to incorporate space and write equations that describe how host and parasitoid densities change at all spatial coordinates. Species that have isolated populations linked by migration are normally described as having a metapopulation structure. Metapopulations are an area of very active research in population biology, although studies of interacting metapopulations, such as that of a parasitoid and its host, are still rare. The most interesting aspect about host–parasitoid metapopulations is that the interaction they describe can persist, even if every component population had been nonpersistent in isolation. For this to happen, component populations must fluctuate out of synchrony so that one population doomed to extinction can be rescued by immigration from a different population in a different phase of the host–parasitoid cycle. Random, local effects that promote asynchrony favor the persistence of a metapopulation, whereas regional fluctuations in characteristics such as climate will tend to synchronize populations and hence act against persistence.

In fully spatial models, the rescue effect can still operate, but now more elaborate spatial processes can also be observed. For example, a wave of hosts can spread through the environment, chased by a following wave of parasitoids. The hosts escape parasitoids by moving into uncolonized areas ahead of the advancing waves, whereas the parasitoid destroys the host population behind the wave front and would itself be destroyed were it not able to chase the host population. These waves tend to form spiral patterns, a feature common to many spatial interactions in population dynamics, physiology, and even inorganic chemistry. For certain parameter combinations, the organized spiral waves break down into a seemingly random jumble of interactions and short-lived wave fronts called spatial chaos. Experimental studies of spatially extended parasitoid populations are still somewhat behind theory and

one of the greatest challenges of contemporary host-parasitoid population dynamics is to devise ways of studying spatial dynamics in the field.

Community Ecology

Few, if any, host-parasitoid interactions exist in isolation: most parasitoids attack more than one species of host, and the majority of hosts is attacked by several species of parasitoid. How does one begin to understand the workings of a large community of interacting hosts and parasitoids? One approach is to build up from the simple one-host, one-parasitoid interactions discussed previously. Alternatively, one can survey the properties of real communities and try to deduce patterns that may reveal how they are structured.

The simplest possible community that is more complex than those discussed previously consists of one host and two parasitoids, or two hosts attacked by a common parasitoid. Both tell us interesting things. In the first case, the simplest models predict that one of the two parasitoids will invariably go extinct. This is a corollary of a basic finding in population ecology that identical species cannot coexist on the same resource—the competitive exclusion principle. For coexistence to occur, other factors must be brought into play. In particular, coexistence can occur if the ecological niche (i.e., the host) is divided in such a way that the parasitoids are no longer identical. Thus, one parasitoid may use the host at one time of year or in one microhabitat, or it may specialize on a different developmental stage of the host from the other. Coexistence can also occur by a more statistical route if hosts differ in their susceptibility to attack by parasitoids. If some hosts happen to be protected from one species of parasitoid by being in the “statistical refuge” discussed above, and if others are independently protected from a second parasitoid species, then this can promote coexistence. Spatial processes can also promote coexistence. Consider two species of parasitoid, one of which is always the winner in a straight competition at a single locality, while the other has a superior dispersal capability. Coexistence is now possible in an environment in which new host populations are constantly being generated because the poorer competitor is able to find unexploited hosts: this is known as a competition–colonization trade-off.

I now discuss the two-host, one-parasitoid case. Again, the simple models predict extinction, this time of one of the host populations. This occurs because the equilibrium population of parasitoids maintained on the surviving host species is sufficient to prevent the second host species from replacing itself. A recent laboratory experiment cleverly illustrated this using two flour moths attacked by the same species of wasp. This is a similar situation to competitive exclusion, but the trophic structure is reversed: instead of two species competing for the same resource, two species are subject to the same natural enemy. In fact, there are deep biological and mathematical symmetries between these two cases, and this has led to the phenomenon of two species interacting through a common natural enemy being referred to as apparent competition to stress the parallels with direct competition, in which two species interact through a common resource. Again, for a two-host, one-parasitoid system to persist, something

extra must be added to the simplest models: the two hosts might be present at different times of the year or might be spatially segregated, or the parasitoids might preferentially exploit the most abundant host (behavioral switching).

Much of traditional community ecology has stressed how biological communities may be structured by resource competition, and thus it does not apply to many insect communities in which the majority of species feed on different host plants and thus never come into contact. Apparent competition is significant because it can at least potentially structure a community in exactly the same way as direct competition does. The degree to which this actually occurs is a major theme in current insect ecology.

Progressing from models of three species to those with larger numbers of components becomes increasingly difficult. There are two problems: first, more assumptions have to be made about how different species interact and about the values of large numbers of parameters. Seldom are there field data to reduce this burden of supposition. Second, the dynamic behavior of larger communities becomes increasingly more complicated. For example, a model of a five-species community consisting of two hosts, two specialist parasitoids, and a generalist parasitoid showed the same range of population dynamic behaviors as those exhibited by simpler communities. However, it also showed more complex behaviors in which the full five-species community was unstable with one or more species going extinct, but with the resultant smaller communities, after they had reached equilibria, then being susceptible to invasion by the species that had recently gone extinct. Other multispecies models have shown complex chaotic dynamics. Currently, it is unclear regarding the extent to which the bottom-up approach, modeling explicitly the dynamics of each member of a large community, is a feasible way to approach parasitoid community ecology.

The top-down approach to community ecology consists of searching for patterns in multispecies assemblages that provide evidence of structuring forces. For example, workers have searched for patterns in the number of species of parasitoids attacking different species of hosts. The attraction of this approach is that there are numerous studies in the literature providing information on the parasitoid complexes of different insects. The major result to emerge from these studies is that the host-feeding niche influences parasitoid species numbers. Leaf-mining insects are attacked by the largest number of species, with successively smaller numbers attacking more concealed hosts (gall formers, shoot borers, and root borers) and less-concealed hosts (species living in leaf rolls and ties and those living externally like typical caterpillars). There are two explanations for this pattern. One suggests that the number of parasitoid species that can coexist on a single host is influenced by the fraction of that host's population that inhabits a refuge from (all) parasitoid attack. Proponents of this view argue for a correlation between feeding niche and the size of the refuge. Alternatively, many species are likely to occur on hosts that are taxonomically and ecologically similar to other hosts because there is less of an evolutionary hurdle to overcome in incorporating a new species in a parasitoid's host range. Leaf-mining insects have a far more uniform ecology than insects feeding in other host niches. They are also relatively

taxonomically homogeneous, and this may have facilitated host transfer and broad parasitoid host ranges.

There are less data in the literature on the host range of parasitoids because this requires all potential hosts in an area to be surveyed. However, the data that are available support one major conclusion: idiobionts have broader host ranges than koinobionts. Recall that idiobionts kill or permanently paralyze their host at oviposition, whereas koinobionts delay development until the host is fully grown. During this suspension of growth, the parasitoid has to cope with the attack by the host's immune system, and the need to evolve to be finely attuned to the host to counteract its defenses probably limits the koinobiont host range.

A different top-down approach to parasitoid community ecology has recently been taken by a few groups, although it is still too soon to assess its value. There is a long tradition of constructing food webs in ecology, and one of the aims of this research program is to search for patterns that are common across different webs. A major limitation of this research is the heterogeneity in published food webs, which are typically collected in very different ways and which differ greatly in their taxonomic resolution. Host–parasitoid interactions have many advantages for food web studies, the most prominent of which is the relative ease with which trophic links can be identified and quantified. This has led to the construction of several quantitative food webs in which all hosts, parasitoids, and links are expressed in the same units. The webs published to date illustrate the extent to which different hosts are linked by shared natural enemies and also the extent to which indirect effects such as apparent competition may act as forces structuring the community. Of course, a limitation of this approach is that only one guild of natural enemies is included in the web, but it will be interesting to determine whether common patterns emerge as more communities are studied.

The Importance of Parasitoids

Why are parasitoids important to students of biodiversity? First, they are abundant members of nearly all terrestrial communities. The populations of few herbivorous insects are unaffected by parasitoid attack, and understanding how they influence and possibly regulate the densities of their host is immensely important in understanding the mechanisms underlying biodiversity. Much of the modern work in parasitoid ecology has been motivated by these considerations.

The second reason why parasitoids are important and why there is such an enormous and valuable literature on parasitoids dating back nearly a century is that parasitoids are our allies in the war against agricultural and forestry pests. There are two main strategies of parasitoid biological control: classical and inundative. In classical biological control, a parasitoid is released into an area to control a pest. Typically, the pest is a nonnative species that has been accidentally introduced into a new region, and normally the parasitoid is a species that attacks the pest in its region of origin. The parasitoid is released once or on a few occasions until it is established. Although only 10–20% of biological attempts are successful, they can have dramatic effects in controlling pests, and the savings in crop

yield are normally many multiples of the investment in the biological control program. There are interesting patterns in the probability of success against different hosts, for example, biological control has an excellent record against scale insects and mealy bugs but is far less successful against aphids.

The second strategy is inundative release in which large numbers of parasitoids are released onto a crop to destroy a pest. Applications are made as often as required, and long-term establishment of the parasitoid (which is normally already there at low density) is not a goal. In effect, the parasitoid is acting here as a biological insecticide. There are two main situations in which this strategy is used today. The first is when labor is relatively cheap so that the costs of mass rearing the parasitoids are not too great. In many tropical countries, huge numbers of egg parasitoids are mass reared and released to attack cutworms, armyworms, and bollworms. Advances in the mechanization of mass rearing are making inundative release more attractive in developed, high-wage countries. The second situation concerns high-value crops in enclosed growing conditions such as greenhouses. Control of tomato whitefly is typically by parasitoids in northern Europe. Inundative control has been favored in these situations because of the decreased tolerance of insecticide residues by regulatory authorities and because of the general need to reduce chemical input so as not to disrupt insect pollination and the existing successful biological control of other pests.

In the post-“Silent Spring” era, biological control has often been viewed as an unmitigated good (particularly by bio-control workers) because it does not involve pesticides. However, in recent years, increasing attention has been paid to the dangers of biological invasions, particularly by plants, and this has led to a reassessment of biological control and to worries regarding the effect of introduced parasitoids on native insects. These are important issues and need to be carefully scrutinized, although there is a real danger of an overreaction and a return to the automatic reliance on environmentally harmful chemical insecticides. Currently, the major problem is a lack of good data on the consequences of biological control introductions. The challenge to applied ecological entomologists is to develop a sufficient understanding of parasitoid population and community ecology building on the ideas described previously, so that they can provide rules and guidelines that will ensure that biological control has a net positive rather than negative effect on biodiversity.

Glossary

Beak (or rostrum) Thin elongate mouthparts, adapted for piercing the organisms on which the bugs feed (the mouthparts of bugs are similar in function to, but quite different in structure from, those of mosquitoes).

Food pump Sclerotized pump used by hemipterans to suck up the juices (plant or animal) on which they feed.

Hemelytron Heteropteran's forewing; so called because the anterior part of the wing is opaque and the posterior part is clear (membranous).

Salivary pump Sclerotized pump used by hemipterans to inject saliva into the organisms on which they feed.

Scent glands Glands through which heteropterans secrete various compounds for various purposes, including defense, attraction of mates, and attraction of both sexes.

Adult heteropterans have scent glands on their metathoraces, and nymphal heteropterans as well as some adults have scent glands on the dorsa of their abdomens.

Scutellum The dorsal portion of the mesothorax, in most heteropterans triangular or shield-shaped (hence "little shield").

Suborders of Hemiptera

The number of actual suborders has recently come into question, because of the uncertain validity of Homoptera. However, three suborders are frequently accepted in most entomology texts: Homoptera, Heteroptera, and Coleorrhyncha. Nevertheless, many homopterists recognize two orders, Homoptera and Hemiptera (= Heteroptera). The reasons for this confusion are themselves confusing and have to do with the importance that heteropterists and homopterists give to the groups they study; this importance in turn is based on the extent to which the students of one group understand the work of the students in the other groups. Those who have undertaken the most thorough study of all hemipteran groups conclude that they share too many characteristics to be treated as separate orders.

"Homoptera"

This group includes the cicadas, leafhoppers, aphids, scale insects, whiteflies, and their relatives. Nearly all feed on plants (a few on fungi), and are not predacious; and many are important pests of crops and ornamentals. Recent work on the origins and (especially) the evolutionary relationships of groups within "Homoptera" has led to the conclusion that the group did not have a unique ancestor common to all homopterans and to no other hemipterans. As a result, the higher classification of "Homoptera," and the systematic status of the group itself, are deeply in question. That is why the author places the term "Homoptera" in quotation marks: The term is useful in grouping together a number of insects, but it is not useful in suggesting they compose a single evolutionary unit.

Coleorrhyncha

Members of the single family (Peloridiidae) have a classic Gondwana distribution: Australia, New Zealand, southern South America. They are associated with moss in *Nothofagus* (southern beech) forests and probably feed on the moss.

Small, somewhat flattened, often with lovely semitransparent expansions of the head and thorax, these insects are poorly known and deserve much more study. Some believe Coleorrhyncha (formerly included in Homoptera) to be the sister group of Heteroptera – that is, that these two groups had a common ancestor. The evidence for this conclusion is stronger than that for the earlier inclusion of coleorrhynchans in Homoptera, where they were once thought to be a sort of "nonmissing link" between Heteroptera and Homoptera. Recently a fine monograph on coleorrhynchans, with 13 genera and 37 species, was written by Burckhardt (2009); this also includes the biogeography of these interesting insects.

Suborder Heteroptera

There are about 42,000 described species of Heteroptera (Henry, 2009) and (a much rougher estimate) perhaps 25,000 species remaining to be described: a total of about 67,000 species of Heteroptera altogether. (Note: In what follows, the estimates of groups of Heteroptera come from Henry (2009).) This estimate may understate the number of undescribed species. Like all hemipterans, they feed by piercing other organisms and sucking their juices. Unlike Homoptera and Coleorrhyncha, however, Heteroptera includes many predacious insects, and many aquatic ones. Heteroptera are more closely allied (evolutionarily) with Coleorrhyncha than with Homoptera, although some have recently argued that the closest relatives of Heteroptera are certain homopteran groups.

Heteroptera: General

Why "True" Bugs?

Heteropterans are the only group of insects that entomologists agree may legitimately be called "bugs"; hence the name entomologists themselves use, "true bugs." Nonentomologists call all insects (and other arthropods) "bugs," and, although entomologists disapprove, they are resigned to this use.

Why are heteropterans called “bugs”? The reason almost certainly lies in the original Middle English meaning of the word: “bug” (as *bugge*) meant originally a *wraith* or *specter*, something unseen that emerges from the shadows and does harm. This is exactly what the best known heteropteran does: the bedbug (*Cimex lectularius* L.) sucks blood from the sleeping victim and disappears; in the morning only the irritating welt from the bite remains, its cause and origin unknown. Clearly, an unseen nocturnal shadow has caused this damage: a bug. (This original meaning of *bugge* is retained in Modern English in such words as *bugbear*, *bugaboo*, and *bogeyman*; one may also wonder if it is retained in the verb “to bug,” meaning (1) to irritate and (2) to use a small and secret device for spying – a form of damage.)

Characteristics

Heteropterans share many structural features with other insects, of course; other features with other insects with incomplete metamorphosis; and of course some characteristics with other hemipterans. Still more aspects of their morphology are unique. A superb early account of structure and function is given in Weber (1930).

Like all insects, heteropterans have three basic body regions: head, thorax, abdomen; and, like those of nearly all insects, these regions are specialized: the head for grasping and preparing food and for exploring the environment, the thorax (with legs and wings) for locomotion, and the abdomen for processing food and for reproduction. Like most insects, heteropterans have three pairs of five-jointed legs and two pairs of wings, a pair of compound eyes (usually large, because true bugs are mostly diurnal and therefore sight is an important sense), a pair of antennae, and an aedeagus (or penis) for the introduction of sperm into the female, who in turn has an ovipositor for laying eggs.

Like other insects with incomplete metamorphosis, immature bugs look like their adults, except for the lack of functional wings and genitalia and for different body proportions. As the immatures develop, wings appear externally as small pads, which enlarge at each molt; later, the genitalia too may be discerned, and often the last immature stage can be sexed.

Heteropterans share more specific features with other hemipterans: The mouthparts are modified into a long sharp tube, with two internal openings. Through one of these, salivary fluid is pumped into the plant or animal (plant only, in the case of nonheteropteran hemipterans), and through the other opening the fluids are sucked up. A set of pumps within the head accomplishes these activities. This mechanism and method of feeding are perhaps the best evidence that all hemipterans are closely related, and this in turn is why most entomologists consider all hemipterans to compose a single order.

Heteropterans, like other hemipterans, have certain characteristic features of the digestive system and the excretory system (although heteropterans lack the “filter chamber” independently evolved in several homopteran groups). The primitive 12–13 ganglia of the ventral nervous system are fused to a single one (or to four in a few homopteran groups). The wing venation is reduced (less so in many homopterans);

the chromosomes are holocentric (diffuse centromere). Many hemipterans can produce sounds, usually by scraping a “pick” over a corrugated surface. Often these structures appear the same and occur on the same parts of the body. But in most cases, these sound-producing structures have evolved independently; the appearance is constrained by their function, and their occurrence on the same body parts is constrained by the fact one body part must move and be in contact with an unmoving part.

Heteropterans themselves are more diverse in habit and habitat than the other hemipteran groups. Heteroptera contains the only hemipterans that live in, and sometimes on, the water; the only hemipterans that are partly marine; the only carnivorous hemipterans; and the only hemipterans that feed on vertebrate (including human) blood. It is not surprising, then, that within the suborder Heteroptera is a wide variety of sizes and shapes, nor is it surprising that structures of heteropterans (legs, etc.) are highly modified in some groups.

The beak, or rostrum, characteristic of Hemiptera in general, in some plant-feeding heteropterans may be longer than the body, and in some predacious heteropterans be so short as not to reach the thorax. It may be slender or stout, and the number of segments may be reduced from the original five. The beak arises closer to the back of the head in heteropterans than in homopterans, and thus a region of the head lies just in front of the rostrum’s base; the presence of this region in coleorrhynchans is one reason why Coleorrhyncha and Heteroptera are thought to have had a common ancestor.

Highly characteristic of Heteroptera alone is the division of the forewing into two regions, the posterior one, clear and membranous (like the hindwing), and the anterior portion, harder, often leathery, and opaque: hence the name “heteroptera” (“different wings”). The two wings on each side are coupled together with a device on the forewing; this is found only in Heteroptera and Coleorrhyncha. Heteropteran sperm, too, has some unique features; coleorrhynchan sperm has not been examined.

Characteristic of nearly all heteropterans is a triangular (pointing backward) part of the top of the thorax, the *scutellum* (“little shield”); in a few heteropterans, especially in the group Pentatomoidea, the scutellum covers all or most of the dorsal surface of the insect, except the head (but including the wings).

Unique to Heteroptera are scent glands. These are found on the abdomen of immature heteropterans (from one to four pairs on either side of the midline). These glands are usually nonfunctional in adults, although in many species they do produce scent; the known number of such species is increasing with increasing study, and the function of the scent from these dorsal abdominal glands is becoming more clear. Adult heteropterans have a pair of glands (regardless of their possession of functional dorsal glands) on the last (third) thoracic segment. These lateral metathoracic scent glands are thought to repel predators (and have been shown to repel ants), but they certainly have other functions as well, including the attraction of conspecifics of the opposite (and sometimes of both) sex(es).

Heteroptera do not differ biologically from other insects and other hemipterans. They do the three basic things that all organisms do – feed, reproduce, and disperse – and, because these things are basic to survival as a species, bugs do them as

much as other winged insects. However, bugs are remarkably more diverse than other hemipterans (and indeed than other insects with incomplete metamorphosis) in their choices of food and of habitats and in their interactions with their environments (for the latter, see below).

Heteropterans feed like other hemipterans. Their sharp elongated mouthparts are adapted for piercing; one internal pump pushes saliva into the food source, and another sucks back the food. In most cases, this food has been all or partly digested by salivary enzymes. Few bugs feed on the watery contents of the xylem in plants, and so bugs lack the filter chamber that in many homopterans removes and excretes excess water (and sugars). (Diuresis does occur in blood-sucking bugs, however: see below.)

The salivary enzymes and substances of plant-feeding bugs serve other functions than digestion alone. Many phytophagous bugs form a small feeding cone on the surface of the plant where the mouthparts are inserted. This cone, made from salivary secretions, helps stabilize the mouthparts as they penetrate to the source of food. Other salivary products help break down cell walls and release the cell contents; other products mimic plant auxins and “fool” the plant into mobilizing nitrogen-rich materials at the point of feeding.

As a general rule, with many exceptions, plant-feeding heteropterans feed on the highly nutritional reproductive parts of plants – flowers, developing fruits and seeds, ripened fruits and seeds, and fallen fruits and seeds. This may be a matter of size: Many plant-feeding bugs are relatively large (i.e., larger than the majority of homopterans); larger hemipterans are better able to penetrate plant parts to the seeds within and to disperse to find flowers, fruits, and seeds – which are transitory resources. Smaller heteropterans, like many homopterans, feed on leaves, a resource more permanent, easier to penetrate, but of less nutritional value.

The flat bugs (Aradomorpha – see below) have very long, very slender mouthparts with which they feed on the linear array of fungal mycelia below the bark of dead or dying trees. A few of these bugs live in termite nests, where they probably feed also on fungi. With very few exceptions, these are the only bugs that feed on fungi.

Indeed, the great majority of phytophagous heteropterans feeds on flowering plants, angiosperms. Several small groups feed on gymnosperms, and a very few bugs feed on mosses or ferns. It seems likely that the great radiation of heteropterans – like the radiations of so many other insect groups – occurred at the same time as, and perhaps in response to, the radiation of flowering plants.

Within the angiosperms, some groups are less preferred than others: grasses, for example, and legumes. Each of these groups has developed defenses against being eaten, and in each case one or more groups of bugs has overcome the defense and radiated on the plant group. It is significant that these two groups (grasses and legumes) have few *individual* species feeding on them but, rather, a few groups of species (subfamilies, families). This suggests that an early ancestor broached the defense (of grass or legume) and its descendants radiated on this newly available food source.

Many bugs are predacious. Indeed, it has been argued that this was the original way of life of Heteroptera (an argument that some dispute). The prey is other insects and often their

eggs or other immature stages. Some of the smallest heteropterans are predacious, on arthropod eggs, mites, and scale insects and aphids. It was long thought that predacious bugs inserted their mouthparts and sucked up fluids inside the prey, much as plant feeders suck sap. Recently, it has been demonstrated how much more complex, and interesting, the situation really is (Cohen, 1998). A predacious bug actively pumps digestive enzymes and fluid into the prey. The enzymes digest the soft internal organs of the prey, and the fluid and digested food are sucked up. This “solid-to-liquid feeding” process is repeated over and over, the mouthparts within the prey moving throughout its body, probing even into the legs and antennae to digest the muscles there. There remains but a husk, a shell, the exoskeleton of the prey, all internal organs having been digested, liquefied, and sucked into the predator. As a consequence, a predacious bug need feed on only a few prey, because all of the prey except its exoskeleton is eaten. The implications of this for biological control using heteropterans are considerable (see below).

The predacious habit has arisen often in the Heteroptera, secondarily, probably more often than phytophagy. This suggests that the search for more concentrated and usable nitrogen is as important in this group as it is in others.

A few bugs feed on vertebrate blood. Heteropterans’ mouthparts, like those of mosquitoes, are long and sharp, and so adapted for sticking into liquid-filled organisms. It seems inevitable that some would take vertebrate blood, although few feed on birds and none on cold-blooded vertebrates (with one exception). With few exceptions, the vertebrates fed on are small mammals and bats – and man. Members of two closely related families (Polycitenidae and Cimicidae) feed on bats, and a few members of the latter family feed on humans: the bedbugs, some of whose relatives also feed on poultry. Members of the assassin bug subfamily Triatominae feed on small mammals, and some of them on humans; these spread the protozoan trypanosome which causes Chagas disease.

The problem of feeding on vertebrate blood includes the problem of ingesting red blood cells through a narrow tube. The physics of this type of feeding have been studied, and maximal feeding is related to the inside diameter of the feeding tube, the concentration of red blood cells, and the duration of feeding. Such feeding also results in the accumulation of blood fluids. These are excreted (diuresis) in a manner roughly analogous to the excretion of plant juices by homopterans (“honeydew”).

Two other heteropterans feed on vertebrates: a birdnest-living lygaeid (the “seed bug” family) apparently feeds only on the blood of the host bird; another group of lygaeids apparently feeds on small mammals in Africa (and may there occupy the niche occupied in Latin America by Triatominae). Giant water bugs (Belostomatidae) have been reported to attack baby ducklings (this may be a legend), and some species specialize in taking the fluids of small fish.

No heteropterans feed exclusively on dead or decaying organic matter (i.e., none is a saprophage). However, there are many anecdotal accounts of various bugs found feeding on bird droppings, carrion, and dead insects. It is likely these bugs sought water or a source of concentrated soluble nitrogen.

The great majority of heteropterans reproduce like other insects: Sexes find one another, there may be a brief period of

courtship, mating occurs (fertilization is internal), and the fertilized eggs are laid near or on the appropriate food for the young.

The sexes find one another probably *via* sex attractants given off by one or the other sex, or perhaps by both (depending on the species; however, very few species have been studied). Courtship, if it occurs at all, is brief. In a few species, males fight for females; the enlarged legs of certain males are used to knock one another off a leaf to which sex attractants are drawing females. However, there seems to be very little intrasexual rivalry in Heteroptera. Mating is often end-to-end, or in many species the male lies at an angle across the female; in all cases both sexes are ventralside down. In some end-to-end species, the female, larger than the male, may be spotted moving around dragging her mate with her; or she may feed casually on a leaf, with the smaller male dangling helplessly in the air, attached only by the genitalia.

Soon after mating occurs, eggs are laid singly, or in characteristic batches, sometimes in several layers, depending on the species and, often, on the family. A female lays several batches of eggs in her lifetime, each one usually requiring a separate mating. The eggs of many species have tiny openings (micropyles) through which the sperm enter; other small openings (aeropyles) provide gas exchange; and some species' eggs have a round or oval line of weakening, through which the insect will hatch.

Eggs may be round, oval(!), cylindrical, or barrel-shaped. Many are brightly colored. The egg of Rhopalidae ("scentless plantbugs") is mounted on an elongate pedicel (like eggs of some neuropterans), presumably to protect it from predators.

Parental care of the eggs occurs in a few species. As is well known, the female of some giant water bugs (Belostomatidae) glues her eggs onto the back of the male, who carries them until they hatch. By sweeping water across them, he keeps them aerated and prevents the attack of fungi. The females of some stinkbugs (Acanthosomatidae) and some lace bugs (Tingidae) protect their eggs and early immature stages, guarding them from attack from parasites and such predators as ants. Experiments have shown that in all these instances, the protection is effective.

The author stresses, however, that with respect to reproduction, as with respect to feeding and all other aspects of heteropterans' lives, we know very little about the lives of some bugs, and nothing about the lives of most.

One strange exception, unique to a few heteropterans, is "traumatic insemination." One of the male's claspers is sharp and sometimes scimitar-shaped. With it he slashes the female's abdomen and sperm is deposited *via* a duct running along the clasper. The sperm finds its way to the storage receptacle of the female. In the evolutionarily more advanced members of this group, a special pad of tissue on one side of the female's abdomen receives the sperm, which then moves to the storage site, passing on its way *through* the cells. This is the situation in the common bedbug. In evolutionarily less advanced species (certain members of the bedbug's family and some Anthocoridae), there is no such tissue, and the sperm are simply deposited in the abdomen. Counting the resulting mating scars allows one to learn how often a female has been mated.

Like those of most insects, the eggs of heteropterans hatch within the year; often they wait through cold seasons

(in temperate regions) or dry ones (in tropical regions). Hatching often occurs through a weakened area of the egg and is aided by an "egg burster" on the hatchling, which is soon lost.

After hatching, the immature bug molts several times, the last time to adult; five immature stages occur in nearly all bugs, and four in the rest. The first immature of several plant-feeding bugs does not feed. Blood-feeding bugs require a bloodmeal to molt to the next stage; molting may require a full meal in other bugs (especially predacious ones), but in fact the stimulus to molt in nonbloodfeeders is unknown.

Each successive stage is larger than its predecessor, of course, and in each the wings are more fully developed. Development of the wings is so consistent in Heteroptera, that the immature stage can often be determined by the relative development of the wings. The sex can often be detected in fourth-stage, and always in fifth-stage, immatures, as the outlines of the external genitalia become discernible.

In general, the immatures feed on the same organisms as the adults. Predacious immatures may take smaller prey, or they may collaborate in taking larger prey. The young of some plant-feeding bugs feed on different plants than the adults, perhaps in response to differing seasonal availabilities of different plants; perhaps also some plants provide better food for growth and others better food for reproduction.

In temperate regions, most bugs go through a single life cycle, overwintering as egg or adult (there being no pupal stage). Eggs overwinter embedded in twigs or in leaf litter; diapausing adults overwinter in litter or just below the soil surface, near their host plants. In spring, overwintered adults mate, lay eggs, and the hatchlings actively seek food (those of some species do not feed, however). Overwintered eggs hatch usually in midspring and become adult in midsummer or late summer, mating and laying eggs that will overwinter. In warmer regions (and, for some species, in temperate regions), there may be more than one generation in a year, and these may overlap. In regions with dry seasons, adults or eggs may estivate. Aquatic heteropterans may overwinter as eggs in or near the water; several species are active below the ice in temperate-region winter; and adults of water striders and their relatives often overwinter on land, rather far from water.

Heteropterans vary widely in their ecological adaptations, both to the biotic and the abiotic aspects of their habitats. Their relationship with their sources of food is of particular significance, both ecologically and because it is this relationship that determines their impact on humans.

Because heteropterans have sucking mouthparts, they must take in liquid or semiliquid food and can accommodate only the smallest of particulate matter. This constraint lies at the base of their relationships to their food.

Plant-feeding heteropterans vary in their degree of host specificity. Some species feed on only a single species of plant, others on members of the same genus, others on many members of the same plant family; and many bugs feed very widely indeed. One coreid is listed from plants in 90 genera representing 35 plant families! It is of interest that a single genus may contain both very highly host-specific species and species feeding on a great variety of plants; this phenomenon is not restricted to Heteroptera.

Not surprisingly, the more host specific a bug is, the more closely its life cycle is tied to the host's. Eggs hatch when the

preferred parts of the preferred host plant are available: Hatch occurs later in the plant's life cycle if the bug prefers reproductive parts, earlier if the bug prefers somatic parts. The triggers for hatch are not known in nearly all cases. The eggs of some mirids are laid in woody tissue of the host and prepare to hatch when the spring uptake of moisture causes the wood to swell and exert pressure. Several other species of Miridae specialize on grasses, and as these different grasses succeed one another in a field over several weeks, so do the mirids. Again, the dynamics and phenology of this succession remain to be studied.

Mirids in particular, many of which feed on shortlived annuals, are closely tied to their hosts' life cycles. The adults of several species of heteropterans feed on different plants than do the immatures. This may reflect differing needs of the stages: immatures need nutrients for growth, adults need nutrients for reproduction; or, the switch from one host to another may merely reflect the fact that these bugs live longer than the plants preferred by the immatures.

The newly hatched immatures of many phytophagous bugs do not feed at all, or take only water; some species take up symbionts from the egg-shells. This period of time when feeding does not occur may be a "hedge" against a delayed appearance of the host plant. It would be interesting to seek a correlation between species with nonfeeding hatchlings and the uncertainty of their host plants' appearance.

Many heteropterans prey on other insects; a few feed on vertebrates; and only a very few feed, occasionally, on non-insect arthropods. In general, predacious bugs feed on prey of appropriate size: very small predators feed on small prey, such as insect (and mite) eggs, mites, scales, and aphids. Large predators feed on larger prey. However, many larger prey organisms (such as caterpillars) are slow-moving and have defenses against predators on their body surfaces; such organisms are available to predators that avoid the body's surface (by penetrating it with their beaks). And so many small predacious bugs will attack large prey, often collectively; such bugs include small adults and the small early immatures of predators whose adults are large. There is some evidence that the collective effect of the predators' injected digestive enzymes benefits all the predators feeding on the single prey. These collective associations are all of the same species.

Aquatic and semiaquatic bugs are nearly all predacious. Those bugs that live beneath the water's surface prey on other small aquatic invertebrates (although one group of water bugs feeds on snails, and another on small fish). Bugs that live on the water's surface (semiaquatic) prey on land invertebrates that fall into the water and become trapped on its surface.

Predacious bugs – whether land, aquatic, or semiaquatic – are either sit-and-wait predators or stalk-and-pounce predators. The great majority attacks its prey on foot, not in flight.

Bugs that feed on vertebrate blood live associated with their hosts, not on them. The hosts are vertebrates that live in enclosed habitats: burrows, nests, caves – and houses. The bugs spend the day in cracks and crevices in these habitats and, at night, venture forth to feed. When feeding, the bug injects an anti-irritant, so that only later is the fact of feeding known. The host list is rather limited: a few birds that live communally (swallows, domestic poultry, and a few others), humans (which also live communally), and especially bats – two

families of heteropterans (Cimicidae and Polycetenidae) appear to have arisen as specialists on bats. One may speculate that the bedbug itself (family Cimicidae) became acquainted with humans when the latter took shelter from the cold in caves, during early Ice Ages; indeed, the only wild bedbug collected came from a bat cave in the northern Middle East.

Surprisingly little is known about the influence of abiotic factors on the individual lives of heteropterans or on bugs' population or community ecologies.

The effects of, and the reactions of bugs to, light and humidity are very poorly known. A few species disperse (i.e., large numbers move from one place to another, although not at regular intervals), and this movement in a few species is influenced by amount of moonlight. In other cases, dispersal is a response to deteriorating environment, whether physical (drying, for example) or biological (dearth of food). Several such bugs (e.g., species of cotton stainers, *Dysdercus*) lose their flight muscles after such dispersal, presumably to divert resources to reproduction.

The existence of circadian rhythms has been documented as influencing a very few physiological phenomena of a very few bugs.

The greatest enemy of heteropterans is other arthropods – this is of course true of all groups of insects. Small heteropterans are fed on by small predacious arthropods, and large heteropterans by large ones. Large heteropterans are also eaten by insectivorous vertebrates – fish, reptiles, birds, and small mammals. All bugs are attacked by ants.

It has been thought that the scent glands, whose possession is a unique characteristic of heteropterans, are defensive against predators. This is probably so, but it is certainly not their only function. Nevertheless, the few actual experiments and observations that have published support the idea that predators – especially ants and vertebrates – are repelled by the glands' secretions. More work on this is needed.

Many true bugs are brightly colored, arrayed in contrasting patterns of black with red, orange, yellow, or white. These bugs, said to be warningly colored, are assumed to be distasteful to predators (at least, to visually orienting predators, like vertebrates) and to warn such predators away. Experiments with the large milkweed bug (family Lygaeidae) confirm that this is the case. The bug feeds on the intensely bitter sap of milkweed and sequesters the cardenolides (which are also strong ATPase inhibitors); these have no effect on the bug itself.

There are many other bugs with conspicuous patterns like the milkweed bug's. Many of these bugs are also bad-tasting, but certainly many are not. Batesian mimicry (where a palatable organism looks like an unpalatable one, and thereby gains protection) is common in Heteroptera. So is Müllerian mimicry, where two unpalatable species resemble one another and presumably each gains from the protection afforded by the other. The difference between Batesian and Müllerian mimicry is graded, not absolute. Also, we need experimental evidence to show what type of mimicry two phylogenetically different but similar bugs represent.

In making these assessments, one should also realize that the types of patterns, and colors, "available" (in the ecological-evolutionary sense) to these bugs are limited. The dark parts of the pattern must be black or near black, and the colored parts red to yellow, because of pigment limitations. The types of

patterns are also limited by the smallness of the canvas (the insect's body) on which they are to be painted. There may also be some genetic constraint, for many of the patterns are much the same: white spots or a line across the wings, for example (although this may not be for contrast but for pattern disruption; see below). For this reason, similar warning patterns may have arisen by chance, and not from a selective pressure for mimicry.

A few predator-prey mimicry complexes are known. In these, a brightly colored predacious species closely resembles its usual prey. Some have dubbed this "aggressive mimicry," thinking the predator "fools" the prey into allowing approach. This supposes that the prey sees as do human beings, something that is most unlikely. More probably, these are Batesian (or Müllerian) mimicry complexes, and what the prey loses in associating with the predator, it more than gains by being protectively – warningly – colored like the predator. This suggestion needs experimental testing.

Such complexes often involve large populations. Other (nonheteropteran) warningly colored species also live in large populations. Perhaps the mass of bright color warns motile predators (like birds) away from a distance.

Other bugs protect themselves by mimicking inedible bits of their environment. At least seven distantly related families and superfamilies contain species that mimic ants; and within several of these families such mimicry has evolved several times independently. Ants are unattractive as food, because of their high content of formic acid, and many other insects mimic ants. In the Heteroptera there are species that look so much like ants that even experts may be fooled. When mimics look like particular species of ants (rather than like ants in general), they look like *local* species. The immatures of some Alydidae look like small species of ants when young and like larger species of ants as they grow.

Three facts constrain such mimicry: First, large bugs cannot look like ants, because ants are small. Second, the bug must be at least somewhat ant-shaped: slender and elongate. This is probably why ant mimicry has not developed in the very large superfamily Pentatomoidea, whose members are large and squat. Third, ants are characterized by a constriction between thorax and abdomen (the "wasp waist"). Large bugs can do nothing about the first constraint. Small bugs over evolutionary time may overcome the third constraint, by "developing" a similar "waist." However, many true bugs "fake" the constriction: Where on an ant the "waist" would be, the bug (otherwise dark, like an ant) has white markings. Viewed from a slight distance, against the dark background of a branch or the ground, these markings give the appearance of an *absence* of body – hence, a "waist." A sequence of such antlike appearances may be seen in the Arhaphinae, a neotropical group of Largidae, and in the Micrelytrini, a tropical group of Alydidae only distantly related to Largidae. Many unrelated heteropteran ant mimics have one or more dorsal spines, presumably to harm the tender mouth tissues of a vertebrate not deterred by the antlike appearance.

Less common is the mimicry of wasps, which occurs in some adult Alydidae, and doubtless in a few other bugs.

Other heteropterans look like twigs, or leaves, or other things of no interest to a predator. Many run or fly rapidly and erratically.

Many bugs can defend themselves more actively, as anyone who has been "bitten" by a backswimmer or giant water bug knows. Predacious bugs especially, with their stout beaks designed to be driven through the hard exoskeleton of another insect, can defend themselves effectively against vertebrate predators – or against insect collectors.

Aquatic bugs would seem to be a delightful prey for fish. Yet they are not so frequently eaten; indeed, even though trout live in the same streams as water striders, stomach contents indicate the striders are rarely eaten. Many water bugs "bite" fiercely (as most aquatic biologists know), and it seems likely that their scent glands help protect them, although the evidence for this is very slim.

Like many other animals, some true bugs break up their body outline by using spots or lines of white against a dark background (the "zebra effect"); indeed, the antlike appearance of some bugs may have arisen this way. Many Coreidae have a white line, straight or zigzagged, across the dark wings; many Pyrrhocoroidea have white spots in the same place, as do some members of other groups. Like the zebra's white stripes, these bits of white break up the bug's outline and make it more difficult to be seen – especially when moving in an erratic way.

Heteropterans seem not to be heavily parasitized. Some groups of parasites are specialized for parasitizing certain bugs (the subfamily Phasiinae of the dipteran family Tachinidae, for example); the eggs of heteropterans may at times be parasitized by hymenopterans; and certainly some species of heteropterans are quite heavily parasitized. But overall, the group seems less afflicted with parasites than (for example) the Lepidoptera.

The females of some lace bugs (Tingidae) ward off predators and parasites by protecting their eggs and young, and this behavior occurs in a few other heteropteran groups. Some heteropterans bury their eggs partly or completely in the substrate, probably to prevent their being parasitized: Many lace bugs, for example, embed their eggs on the lower surface (less conspicuous) of leaves and cover them with frass, thus concealing them from sight and (perhaps) from scent.

Finally, like all arthropods, heteropterans wear their skeletons on the outside. This makes their bodies hard and often smooth. As a result, several kinds of potential predators (especially ones with jaws) simply cannot grasp or crush heteropterans (or many other arthropods). For example, there are few records of predacious beetles feeding on bugs.

Economic Importance

Many heteropterans are serious pests of crops, and one group transmits the trypanosome protozoan that causes Chagas disease. This group is the Triatominae, a subfamily of assassin bugs (Reduviidae) that lives in the New World Tropics (with a few exceptions) and in which *Trypanosoma cruzi* develops. These bugs feed on vertebrate blood. Several live in association with humans and can transmit *Trypanosoma cruzi* to them. The result is Chagas disease, which afflicts millions of people a year in Latin America, often killing its victims and costing several billions of dollars in lost lives, lost productivity, and disease prevention and treatment (see Schofield, 1994).

A genus of Triatominae lives in India, but so far Chagas disease does not occur there. Very rarely, the disease occurs in the southern United States, where the bugs, the trypanosomes, and the wild rodent hosts all may be found.

More widespread is the damage caused to plant crops by heteropterans. Several species of stinkbugs, called collectively Sunn pests, are the chief destroyers of wheat and barley in a broad swathe from eastern Europe through the Middle East into Pakistan. In parts of this range, these bugs may destroy up to 70% of the crop (see [Javahery, 1995](#)). The southern green stinkbug is a major pest of many crops throughout the world. In the United States, the chinch bug *Blissus leucopterus* (Lygaeoidea: Blissidae) is sometimes a serious pest of wheat. Cotton stainers (Pyrrhocoridae) damage cotton and cotton seed in many semitropical parts of the world (but not the United States). Lygus bugs (Miridae) are very serious pests of a wide variety of crops, especially in the temperate parts of North America. In the last few years, there has been a resurgence of bedbugs, which one expert has called a “pandemic,” in all parts of the world. This “pandemic” has perhaps been caused by the increased movement of people throughout the world. Many other heteropterans are general or specific pests, locally or worldwide, on many crops: A detailed account of these pest insects may be found in [Schaefer and Panizzi \(2000\)](#).

A few heteropterans are important in biological control. A very few feed on weeds and provide some control. Many are predacious and feed on other insects. However, like most predators, most heteropterans are not prey-specific and cannot usually be depended on to control completely pests on a crop; moreover, they do not feed on many prey items. These insects would serve better as components of an Integrated Control Program. Among the families that have been studied are Reduviidae, Berytidae, Nabidae, Anthocoridae, (some) Miridae, Geocoridae, and Pentatomidae: Asopinae; members of several aquatic families have been tried in controlling mosquitoes, without much success (see [Schaefer and Panizzi, 2000](#)).

As noted above, predacious heteropterans feed on only a few prey. When it was believed that these bugs removed from their prey only the latter's liquids, it was also thought that each predator must feed on many prey in order to get enough nourishment. Now we know this is not so. As a result, those using these bugs in biocontrol programs must rethink the bugs' efficiency, because each bug actually feeds on far fewer prey items than had been thought. Many prey-predator models, and considerable biocontrol planning, have been rendered invalid by the recent discovery of this mode of feeding ([Cohen, 1998](#)).

Heteroptera: Specific

The suborder Heteroptera contains eight infraorders: Enicocephalomorpha, Dipsocoromorpha, Gerromorpha, Leptopodomorpha, Nepomorpha, Cimicomorpha, Pentatomomorpha, and Aradomorpha; “-morpha” means “in the form of,” and each infraorder is derived from the generic name of a member. Hence the often pen- and tongue-shattering concatenation of syllables. These groups, and the families that compose them,

are discussed very well in [Schuh and Slater \(1995\)](#), and, in less detail, by [Henry \(2009\)](#) and [Schaefer \(2009\)](#).

Of these, the first two infraorders contain relatively few species (400 and 320, respectively), of poorly known insects; these are all predacious and many live in or on ground debris; it is certain that many more species will be discovered when this type of habitat is explored in the Tropics. They are of interest because they are phylogenetically primitive.

The Gerromorpha contain about 2000 species, many of them in the Gerridae, the water striders, or water skaters, or “Jesus bugs,” which are common everywhere skimming the surface of still waters or the edges of moving waters. Here they capture insects that fall into the water; they rarely if ever capture aquatic organisms. One group of water striders is among the very few insects that live on or in saltwater: the marine water striders live on the ocean's surface, often far from land. Because they live on the water, not in it, gerromorphans are called “semiaquatic” bugs, or, in an earlier terminology, Amphibicorisae.

The Leptopodomorpha too are semiaquatic, most of the 380 or so species living near water but neither on it nor in it; a few species live in the splash zone of the sea. All are predacious. Most belong to the family Saldidae, the shore bugs, which are fairly common on rocks in or near water, where their ability to jump and conceal themselves in crevices frustrates the best of collectors.

The 2300 species of Nepomorpha, aquatic bugs (Hydrocorisae), live below the water's surface. Here are the familiar backswimmers (Notonectidae), water boatmen (Corixidae), giant water bugs (Belostomatidae; some Indian species may reach 4 inches in length), and water scorpions (Nepidae); there are several other nepomorphans families that have more tropical species than temperate. All of these are predacious, although water boatmen feed also on freshwater algae. Some giant water bugs specialize on freshwater snails and may be useful in controlling those harboring the schistosomiasis platyhelminth. Others sometimes cause some damage in fisheries, where they may attack young fish. From time to time, someone suggests using some of these aquatic bugs to control mosquitoes, but the attempts have yet to succeed.

The Cimicomorpha, with more than 26,400 species, is the largest of the heteropteran infraorders. This is because it contains the Miridae, or plant bugs, which, with almost 10,400 species, is the largest heteropteran family. Cimicomorpha also hold the Reduviidae, whose 6900 species make it the second-largest heteropteran family. Cimicomorphans are basically (primitively) predacious, but several groups have secondarily become phytophagous: the small family Thaumastocoridae (19 species) feeds on palms; the Tingidae (2100 species), or lace bugs, feeds on leaves of many plants and may occasionally become serious pests; and most members of the Miridae feed on plants, although many mirids are predacious. It is possible that the evolutionary success of Miridae (as reflected in the family's many species) derives from mirids' association with annual weedy plants, plants that grow rapidly and yield to other species; mirids, too, develop rapidly, and many are quite host specific. Many of the predacious Miridae are site-specific, living on a single species of plant. If the plant should be of economic significance, these mirids can be useful in biological control.

Of the wholly predacious groups, the assassin bugs, Reduviidae, are the most important. Some are specialists (unusual for predators), one group feeding on millipedes, another living in spider webs and stealing food from the spider; yet another feeds on termites and sometimes lures them from the mound. The group's biocontrol potential has been little studied, except recently in southern India (see Schaefer and Panizzi, 2000; Ambrose, 1999). As mentioned above, members of the subfamily Triatominae feed on vertebrate blood, and the neotropical members transmit the Chagas disease trypanosome to humans.

All 110 species of another cimicomorphan group, Cimicidae, feed on vertebrate blood, especially on that of cave-dwelling vertebrates such as bats, communally nesting birds – and (earlier) man. The bedbugs (*Cimex lectularius* L. and *C. hemipterus* (Fabricius)) are parasites of man. *C. lectularius* feeds only on man and is one of a very few insects that occur only with man (the housefly and the head and body louse are among the others). *Cimex hemipterus* is at times a pest of poultry. *C. lectularius* is primarily a temperate-zone species, although it extends into the Tropics; *C. hemipterus* is tropical.

Other important cimicomorphan groups include the damsel bugs (Nabidae), a worldwide family of nearly 400 species, common in crop fields in North America and often studied for their biocontrol potential; and Anthocoridae, minute flower bugs, a group (440 species), also worldwide, of very small and often strikingly patterned insects much studied for their control of pests, especially in greenhouses.

The seventh infraorder, Pentatomomorpha, is also large, with at least 16,200 species. One of its families is third largest in the Heteroptera: Pentatomidae, with about 4700 described species (Note: In what was once called the "Lygaeidae," there were nearly 3600 species, which would make this the fourth largest family in Heteroptera. However, many of these subfamilies have been raised to family rank, and are now part of the superfamily Lygaeoidea (Henry, 1997).) Pentatomomorpha is one of only two infraorders that appear to have arisen as plant feeders, although one important subgroup, the subfamily Asopinae (family Pentatomidae), is secondarily predacious and important in biocontrol programs. Most pentatomomorphs feed on the nitrogen-rich reproductive parts of plants, especially on their ripe and ripening seeds. Pentatomomorpha is also the most difficult infraorder to spell correctly.

A major pentatomomorph group is the Lygaeoidea (see above), or seed bugs and milkweed bugs; most of these feed on seeds, although a few groups feed on grasses and members of one of these, Blissidae (435 species) or chinch bugs, sometimes become pests on wheat and grass (including turf). Another major group is the Pentatomidae (stinkbugs) (4700 species), which also feed on reproductive parts, although many others feed on somatic tissue. Included here is the southern green stinkbug, *Nezara viridula* (L.), a major pest of many crops across the world. Here also are the Sunn pests, a group of pentatomids and some Scutelleridae (a family closely related to Pentatomidae; 450 species) that ravage wheat and barley throughout the Middle East and surrounding areas. Several small families are related to Pentatomidae, including the Cydnidae (765 species), many of which live in the soil and suck from the roots of plants. Members of Scutelleridae are often brilliantly and iridescently colored

(although Sunn pests are not). Females of many Acanthosomatidae (nearly 200 species) guard their eggs from parasites and their young from predators.

The Coreidae (leaf-footed bugs) (nearly 1900 species) and Pyrrhocoridae (cotton stainers) (340 species) are related to Lygaeoidea. The former includes the squash bug (*Anasa tristis* (De Geer)) and a group of bugs with expansions on their legs ("leaf-footed" bugs); some of the latter (in the Neotropics) are brilliantly colored, and others (in North America) come to houses for warmth when winter sets in. The largest genus in Pyrrhocoridae is the tropical *Dysdercus*, many of whose species are serious pests of cotton, which they damage in part by direct feeding on the seeds. Greater damage is caused by their feeding punctures' providing entry into the cotton boll of boll rot disease organisms; these organisms, and the bugs' excreta, destroy and stain the cotton fibers (hence "cotton stainers"). One other species, the European *Pyrrhocoris apterus* L., is famous for its role in the discovery of "paper factor," a discovery that led to the development of natural and artificial juvenile hormone analogs, useful in insect control.

The last (eighth) infraorder is Aradomorpha (about 1940 species), also a plant-feeder, and until recently included as a member (superfamily Aradoidea) of the Pentatomomorpha, from whose other members it differs in several significant respects. Among these are the long mouthparts and the lack of long sensory hairs arranged in characteristic patterns on the underside of the abdomen; pentatomomorphs have shorter mouthparts (like those of other heteropterans) and have these abdominal sensory hairs (unlike most other heteropterans).

The Aradomorpha are a small group of brownish to grayish flattened bugs, nearly all of which live under the bark of dead or dying trees, where they feed on the long mycelia of fungi; adapted for this are the very long very slender mouthparts, which at rest are kept coiled in a special pouch within the head. These bugs range from about 3 to 10 mm long and are often wingless; the upper surface of the body is frequently "bumpy" or pebbly and the legs and antennae are short. One species, *Aradus cinnamomeus* Panzer, differs from the others and feeds on the sap of several pine species; from time to time it becomes a serious pest of commercial pines in northern Europe. It has a 2-year life cycle, and the discovery that some populations reproduce in odd-numbered years, and others in even-numbered years, has led to interesting biogeographical and population studies. Nine other species (family Termitaphididae), distantly related to all the others (family Aradidae), live in termite nests, where they lay their eggs among the termites. Only a few millimeters long, these bugs lack an ovipositor, eyes, and wings and probably feed on fungi within the nests. Very little indeed is known about them.

Conclusions

Heteropterans share fundamental properties of structure and biology, especially of feeding: their elongated mouthparts so well adapted for the sucking up of the fluids of other organisms. Yet the diversity of heteropterans is remarkable, in size, form, habitat, and structure. Groups now considered rare are probably in fact common, as collecting in habitats hitherto disregarded has shown: Enicocephalomorpha and

Dipsocoromorpha are probably far more common than we believe, but live in soil and debris habitats in the Tropics, habitats no one studies. Recent work on tree-canopy habitats in the Tropics has revealed assemblages of unknown or poorly known heteropterans found (apparently) nowhere else. Too many entomologists have for too long scorned insects that cannot be collected with nets. Once such other collecting methods as searching the ground's surface became common, so did groups (like Lygaeoidea) once thought relatively scarce.

It follows that the diversity of Heteroptera, like the diversity of all other groups, is constrained not by evolution but by man's knowledge and by man's willingness to seek diversity in different habitats: For the diversity is there.

What the author has sketched above is based in truth on a remarkably small number of observations and experiments on a remarkably small number of heteropterans. One hopes those observations are accurate and those heteropterans are representative. Much more work, on many more heteropterans, as well of course as much more collecting, will make even more clear just how diverse and fascinating true bugs are.

Glossary

Chaetae Bristles composed of chitin cylinders glued together by scleroprotein emerging from parapodia or the body wall in many annelids, including most polychaetes and in the oligochaet families of the clitellates, but present in most of all major annelid taxa.

Nuchal organ Sensory organs with nerves coming from the posterior part of the brain or from the nerve ring, usually present as ciliated pits or short ridges at the posterior end of the prostomium, present in most polychaetes species, also present in the sipunculans.

Parapodium Segmentally arranged outpockets from the body wall, usually divided into two branches (rami), the dorsal notopodium and the ventral neuropodium; present in most polychaete species, but extremely variably developed and sometimes entirely absent.

Peristomium Region around the mouth of the larvae; if distinct in adults may carry peristomial cirri.

Prostomium Morphologically anteriormost part of the body; may carry antennae and eyes and carry at least part of the brain.

Segment In annelids a section of body set off from the rest of the body by septae at both ends; containing a separate part of the secondary body cavity (coelom) with paired ventral ganglia, and usually nephridia, gonads, transverse muscles and segmental blood vessels carrying externally parapodia with chaetae and gills in most polychaetes, chaetae in oligochaetes. Distinct segments present in posterior end of siboglinids (pogonophorans and vestimentiferans), indistinct in most other annelids.

Trochophore Larva characteristic especially of annelids and mollusks, consisting of an episphere, a ciliated girdle around the middle called the prototroch, and the hyposphere. In feeding trochophores the mouth is located behind the prototroch and the anus is terminal, usually surrounded by a second ciliated band, called the telotroch. Segmentation takes place between the prototroch and the telotroch and is initiated immediately in front of the telotroch.

Annelida

Traditionally the phylum Annelida consisted of three classes: Polychaeta, Oligochaeta and Hirudinea. The Hirudinea were shown to be derived from one of the oligochaeta groups, so the two groups are now fused to Clitellata. The clitellates have been shown to be closely linked to one of the polychaete groups, so Polychaeta is now considered a paraphyletic group in relation to the clitellates.

Two small, mainly deep-water phyla, Vestimentifera and Pogonophora have been shown to be a single group, and to belong to a single family, Siboglinidae, a sister taxon to the sabellid polychaetes; thus these two phyla are now considered annelids belonging to one of the polychaete groups.

Recently the spoon worms, phylum Echiura, have been linked directly to the annelids, probably most closely related to the clitellates. Finally, the peanut worms, phylum Sipuncula, have been shown to be related to the annelids, but the position is still debated.

One group, Myzostomida, parasitic on echinoderms, was considered a member of the Polychaeta; they were then removed from the Annelida and associated with the Platyhelminthes, but they are now back among the annelid-related groups, in a somewhat uncertain position.

The evidence for this reorganization of many of the worm-like phyla comes only in part from morphology or embryology, the most convincing evidence has been supplied by molecular genetics.

Polychaeta is a commonly encountered group of annelids (segmented worms) best represented in the marine environment, although several species are present in freshwater and a few are known from moist soil on land. The Polychaeta, the many-bristled worms, include about 15,000 described species. Estimates of the total number of species varies, but judging from the rates of description of new species it is likely that more than 20,000 species will eventually be recognized, based on morphological characters in addition to the study of all genetically fixed properties of the worms. No single feature can be used to diagnose the taxon uniquely; until recently the presence of the nuchal organs were considered such a feature, but even this structure is missing in several polychaetes and present in Sipuncula.

Clitellata contains the earth worms and their aquatic relatives and the leeches. The clitellates evolved from the polychaetes, but the exact relationship has not yet been diagnosed.

Morphology

This section is based mainly on the polychaetes, since these are perhaps the most complex of the annelids.

The annelids are composed of three body regions, derived from regions present in the larvae. In the polychaetes the presegmental prostomium and peristomium are followed by a segmented body and a postsegmental pygidium, which carries the anus. Most polychaetes are less than 100 mm in length

with 100 or fewer segments; many are very small, with as few as 10 segments, and are adapted to life between sand grains in sandy beaches. Some species may become very large with 2–3000 segments and lengths between 1 and 3 m; the longest recorded specimen was more than 6 m long when collected in Port Jackson, Australia. These very large worms may be as old as 50–100 years, but the documentation for this is rather poor. In general, small species are short lived compared to larger relatives. Perhaps most polychaetes live 12–18 months, while others go through three or four generations in a year. The general body shapes may be earthworm-like with cylindrical bodies and very little in the way of external appendages, but more usually the protruding parapodia and chaetae make the worms appear ragged. The ventral side may be flattened with two longitudinal ridges on either side of the mid ventral nerve chord; the dorsal side is usually convex. This description fits best for mid-sized free-living worms; the tubicolous worms are often cylindrical with inconspicuous parapodia, the very small species are often slender and the parasitic species may be flattened and disc-shaped.

Of the clitellates the oligochaetes are slender; most aquatic species are small, the terrestrial ones may be very large, such as the giant earthworms present in Australia. The leeches are usually flattened and have suckers developed at one or both ends of the body.

The echiurans are often large, rounded or sausage shaped, without any visible segmentation and with a pair of, or sometimes more, hooks just behind the mouth; the prostomium is spoon shaped or sometimes extremely elongated T-shaped.

The sipunculans are often more or less peanut shaped (hence the common name) when the anterior end is retracted; when this end is extended they become elongated drop shaped with a crown of feeding appendages anteriorly.

Head

The head consists of the prostomium and peristomium in the adults, but one or more of the first segments may be fused to this structure (see [Figures 1–3](#)). The prostomial part may carry antennae and eyes, and the fused anterior segments may have a pair of tentacular cirri per fused segment; these cirri are the dorsal and ventral cirri of each segment participating in the head structure. In Canalipalpata the head end can be complex and the number of segments included in the head may be difficult to count. Some of these worms may have a tentacular crown (e.g., the sabellids and serpulids) or a very large number of antennae (e.g., the terebellids). Certain polychaetes lack anterior appendages entirely (e.g., the capitellids and maldanids).

In clitellates the head consists of the prostomium and peristomium and lacks appendages. In the echiurans the prostomium is most often short and spoon shaped, but may be extremely elongated and distally T-shaped. In the sipunculans the prostomium is a rounded lobe when distinct and the peristomium consists of branching groups of feeding appendages.

Segments

Segments are always added just in front of the pygidium, that is, from the posterior end of the segmented body. They are often first seen as low ridges just in front of the pygidium;

parapodia, chaetae and other externally obvious structures are differentiated as more segments are added and, as a consequence, each segment no longer has the position of the last segment. The total number of segments may be fixed and limited (e.g., 20, 25, etc., in certain polynoids, maldanids and opheliids). In many species the number of segments varies with relatively narrow ranges; for example, many neridid species have 80–120 segments. Some species have an unlimited number of segments and the worm keeps on adding segments throughout life. Normally each segment has a pair of parapodia (see [Figure 4](#)). In many species the parapodia are poorly developed and marked only by the position of the chaetae; in other taxa the parapodia are complex structures with a variety of lobes and lamellae. In well-developed parapodia the two rami often differ. The notopodial are smaller (or shorter) than the neuropodia in many species; when they are completely missing the parapodia are called uniramous. In the identificatory literature a number of terms (e.g., sequiramous) are used to characterize the level of reduction of the notopodia. These terms are used inconsistently and it is better to specify the structure observed than to apply a poorly understood term. When the parapodial are best developed each ramus has a chaetal lobe supporting one or more bundles (or fascicles) of chaetae and pre and postchaetal lamellae covering the bases of the emerging chaetae. The chaetal lobe is supported by one or more acicula in many species. A dorsal cirrus is found on the dorsal edge of the notopodium or on the adjacent body wall and a ventral cirrus is along the ventral edge of the neuropodium; both cirri are mainly sensory structures. In addition to the pre and postchaetal lamellae various other lamellar or finger-shaped structures may be associated with each ramus. A complex terminology is associated with shape and position of each structure. Clitellates have distinct segments, often subdivided into two or more rings, but lack parapodia. In echiurans, larvae may have more or less distinct internal segmentation distinct mainly as groups of muscles; the sipunculans lack distinct segmentation, note however, that the sipunculans have the body cavity separated into an anterior and posterior cavity organized so that the eversion of the anterior end is supported from musculature in the anterior cavity.

The Pygidium

The pygidium may be a rounded or tapering simple structure with the anus opening either dorsally or terminally, but frequently it carries anal (or pygidial) cirri. Commonly one or two pairs of cirri are present, but in some taxa it may be ornamented with numerous cirri or flattened lamellae (e.g., maldanids), and in the opheliids it may have an open hood with many papillae, both inside the hood and along the margin.

In the sipunculans the digestive tract is U-shaped and as a consequence the anus opens at the base of the anterior introvert.

Chaetae

The chaetae, the bristles, may be in bundles, however, in most cases the “bundles” consist of two or more short, oblique rows

of a few chaetae each. Other polychaetes have chaetae arranged in flattened fascicles usually arranged dorsoventrally. Each chaeta is produced from an invaginated epidermal cell (chaetoblast). The outer cell membrane of each chaetoblast is covered with microvilli, each of which produces a slender cylinder of chitin. These cylinders are glued together by scleroprotein produced by cells lining the invagination. All chaetae are formed the same way, through complex interactions between production of cylinders and glue secreted to keep the chaeta together and give the external shape. The chaeta may be tapering capillaries, but most chaetae are much more complex (Figure 5). A species may have a single kind of chaetae or two or more kinds; in some parapodia each chaeta may be different, but more usually groups of chaetae with similar structure are present. New chaetae are formed throughout the life of the worms, and distribution of different kinds of chaetae is carefully controlled and changes as the worm grows. In rows of identical chaetae new chaetae are produced at one end of the fascicle and drop out at the other

end (e.g., hooks in terebellids). In syllids that often have few chaetae, and each chaeta differs from all other chaetae in a parapodium, replacement takes place in a one-to-one fashion. Special kinds of chaetae such as acicula, which are rods supporting long parapodia and various large spines often show signs of wear, an indication that they are not replaced or at least not replaced as often as other chaetae. The base of the chaetae (chaetal sac) is anchored with muscles running across the body cavity, making it possible to protrude and retract the whole fascicle or bundle since in most cases only a single set of muscles are present. Acicula and large spines often have their own investment of muscles and are independently movable.

The oligochaete taxa of the clitellates each have a limited number of kinds of chaetae, most have capillaries or spines. The echiurans have minimally a pair of large hooks, usually located ventrally behind the mouth. The sipunculans lack chaetae, but have epidermal hooks formed directly externally on the body.

The Nervous System

The nervous system consists of a dorsal brain connected by a double nerve ring running around the esophagus to double ventral nerve chords. The anterior part of the brain is located in the prostomium, but penetrates well into the peristomium or even into the next several segments in many species. In most groups the two parts of the ventral nerve chord are wholly or partially fused into a single entity; each segment always contains a pair of ganglia from which the segmental nervous system runs to the parapodial muscles, nephridia, gonads, and circulatory system. The gut is invested from a separate set of nerves from the lower part of the brain (stomatogastric nerves). Antennal nerves run from the anterior part of the brain, and a pair of nerves associated with the

posterior part of the brain runs to the palps. Indeed, Orrhage has found a pattern in the emergence of nerves and internal connections in polychaete brains, showing that the limited number of nerves can be identified from one group to the next based on position and function.

The ventral nerve chord may contain two or more giant fibers associated with rapid retraction into burrows or tubes consisting of very thick nerves running from the anterior end innervating the longitudinal muscles directly with only a minimum of synapses. Other motor fibers are segment-to-segment loops passing along undulatory locomotory waves.

The clitellates have a nervous system resembling the one present in the polychaetes. In other annelids the main nervous system resembles the one present in the polychaetes, but segmented nature of other nerves is absent.

Sense Organs

Eyes are mostly eye-spots located on the prostomium or even directed on the upper surface of the brain. In some polychaetes the eyes become much larger when the species are sexually mature (e.g., nereidids), and the epidermis over the eye becomes a translucent lens. In a group of pelagic polychaetes (e.g., alciopin phyllodocids) the eyes are a very large camera construction with a distinct lens and with focal capabilities of considerable complexity. In the polychaete eyes, the sensory cells penetrate through a pigment layer (retina) into the space in which the lens is supported and the optical

nerve is collected behind the pigment layer, thus the retina is reversed compared to vertebrate eyes.

The nuchal organs are usually located in pits, in short grooves or on short ridges near the junction between the prostomium and the first segment. The nuchal organs may be very large, complexly folded structures (caruncles) in the euprosinids and amphinomids. And the epaulets present in some syllids are also nuchal organs. In some spionids the nuchal organs stretch along most of the anterior region of the worm as narrow, ciliated attached ridges. The presence of nuchal organs has been considered diagnostic for the polychaetes in relation to the clitellates, which lack these

Figure 4 Polychaete parapodia. (a) Amphinomid; note similar rami. (b) Arenicolid; note neuropodia modified to a torus and the musculature linking the base of the chaetae to the ventral body wall. (c) Paralacydoniid; note unequal rami and the notable presence of aciculae. (d) Phyllodocid; note large, foliose dorsal cirrus. (e) Chrysopetalid; note that some of the notopodial chaetae are large, flattened paleae covering the dorsum. (f) Spionid; note the dorsal flattened gill. structures. However, some polychaetes lack nuchal organs, and sensory structures closely similar to the nuchal organs are present in sipunculans, so the presence of these sensory organs may be a shared feature of the annelids and the loss among certain annelids may be a secondary phenomenon.

Ciliated lateral organs are located between the parapodial rami in many polychaetes, they are usually tufts of cilia in a shallow pit, but may form eversible papillae in some taxa. Similarly constructed patches of cilia have been reported from a variety of annelids and may form patterns of sensory organs

characteristic of each of the major groups. All these ciliated structures are assumed to be at least partially chemosensory, but the experimental evidence is usually missing.

Musculature

Musculature includes two pairs of longitudinal muscle bundles; these bundles are usually ovate in cross-section, but

especially in species with massive longitudinal muscles, they are folded over, presumably to avoid buckling during strong contraction. The ventral pair is usually heavier than the dorsal pair, which in some worms (e.g., terebellids) form a thin layer between the upper edge of the notopodial and the dorsal midline. Circular muscles are usually considered to be present; however, at best they are present near the septal boundaries. Most of the other segmental muscles are associated with the parapodia, the chaetae, or are dorsoventral transverse muscles.

Whether these antagonists to the longitudinal muscles represent the remnants of a former complete layer of circular muscles has yet to be determined.

However, it appears likely since most other annelids have the longitudinal muscles represented by a relatively even layer and a distinct circulatory muscle layer is present. The clitellates have longitudinal bundles of muscles, and the small aquatic species lack circular muscles; however, the terrestrial earthworms have a well-developed layer of circular muscles.

Septa

Septa separating the segments are rarely complete, but in many cases they are sufficiently muscularized, with radiating and circular muscles to allow each septum to clamp down around the digestive tract and at least temporarily isolate each segment. In certain families one or more of the anterior septa may be complete (gular membranes) and may isolate an anterior part of the body cavity from the rest of the body.

Other than the polychaetes the septa in other annelids are reduced or missing except the separation isolating an anterior chamber of the body cavity from the rest of the body in the sipunculans.

Digestive Tract

The digestive tract is usually a more or less straight tube running from mouth to anus. The larval stomodaeal region (infolded ectodermal region in the mouth) may be elaborated into an eversible pharynx (proboscis). This pharynx may be axial or may include only the ventral side; it may be sac like or muscular. Jaws are present in some taxa; they are thickened regions of the cuticle and as such consist primarily of sclerotinized protein in which a variety of metal ions may be imbedded, or they may be calcified. Paired salivary glands are often present. The middle of the gut may be invested with a large blood sinus or is at least well supplied with segmental blood vessels. In postlarval siboglinids (Pogonophora and Vestimentifera) the gut is blind ending at both ends and the lumen of the gut is largely obliterated, but a very inflated specialized gut wall is present. The cells of this gut wall contain numerous commensal bacteriae. The scale worms have numerous segmentally arranged blind sacs attached to the midgut; at least some part of the intermediary metabolism takes place in these sacs, which also in part supplements the circulatory system in bringing nutrients to the tissues in which they are needed. Some polychaetes have a looped gut; in these taxa the septation is missing in the region that contains the loop. Looping allows for an increased length of gut in relation to the size of the worms.

The gut in other annelids is most frequently similar to the one in the polychaetes in that it runs from mouth to anus, except that it frequently is rather long and folded. The exception is Siuncula in which the gut is U-shaped, with the ascending and descending parts spiraled around each other. The anus is at the anterior end of the main body at the base of the retractable anterior part of the body.

Gills

Gills are present in a variety of taxa. They are usually associated with the notopodial but may be present anywhere along the body; they are recognizable as thin-walled extensions from the body wall containing a vascular loop in which the two limbs of the loop are linked through capillaries. This definition excludes the structures called gills in capitellids and glycerids, both of which lack a circulatory system; these structures cannot at this time be considered homologous with the gills present in taxa with closed circulatory systems. Functionally, any thin-walled extension from the body wall will have a gas-exchange function whether it structurally belongs to a given category of structure or not. This issue is of considerable phylogenetic interest in that gills must have evolved independently several times, while in other clades, morphologically different structures, including the notopodial cirri, have taken on respiratory functions.

Gills are absent in most nonpolychaete annelids; some leeches have extensions from the body wall with respiratory functions and the anterior feeding apparatus in the sipunculans have a similar function. The echiurans have paired anal sacs that they periodically flush, presumably bringing water into the sacs, which would bring oxygenated water into close proximity to the digestive tract.

Circulatory System

Circulatory systems may be complete, consisting of a dorsal, often contractile vessel, in which the blood flows anteriorly, one or two major ventral vessels, and capillaries connecting these vessels to the gut and to the rest of the organs. Some polychaetes lack the capillary beds and thus have an open circulatory system. And small species often lack a circulatory system entirely, presumably relying on diffusion for transportation of oxygen, carbon dioxide, and so forth. Shared absence of a circulatory system is not considered a feature of phylogenetic importance; it seems to be linked to a reduced body size.

Nephridia

Nephridia may be present already in the larvae as protonephridia; postlarval nephridia may be either protonephridia or metanephridia. Protonephridia open into the body cavity with intracellular slits; metanephridia open with a funnel. In all postlarval polychaetes, the inner end of the nephridia is located in the segment preceding the one in which the duct opens to the exterior. About 100 years ago Goodrich identified a series of possible fusions between the nephridia and the excretory ducts for the gonads (e.g., protonephromixia, metanephromixia, mixonephridia). New information suggests that this classification may not represent the situation accurately, and that it is more complex than previously understood. Nephridia are often present in many segments, especially when the segments are similar in structure; however, in many polychaetes the number of pairs of nephridia may be limited to four or five. Excretory nephridia are always located anterior to nephridia, which functionally become gonoducts when the worms are sexually mature.

Gonads

Gonads may be present in many segments, or they may be limited to several or even just a few segments in the middle of the body. Sexes are most frequently separate, but hermaphroditic taxa are scattered throughout the group. The gonads are usually very simple, part of the peritoneal lining of each segment, sometimes attached to the transverse or oblique muscles. In many polychaetes only the first few cell cleavages leading to eggs and sperm take place in the gonads proper, the rest of the development takes place in the coelomic fluid in which the eggs and sperm float. The developing spermatocytes may have incomplete early mitotic cleavages, leading to flattened sheets or rounded balls of cells in which the head end of the sperm is embedded in the shared structure; these structures are called sperm morulae. The yolk of the developing eggs may be furnished by nurse cells, either in a layer or as two strings. However, in many species no nurse cells are present, but the coelomocytes function at least in part to furnish the building blocks of yolk for the eggs and the general nutrients to the developing sperm.

Reproductive Biology

Most species spawn in the water, the site of fertilization as well as development up to settlement; indeed, several species swarm on the surface, such as the palolo worms of tropical waters, sometimes while emitting luminescence (e.g., *Odontosyllis*). A few species have modified some of the parapodia for copulation, but this is rare and limited to certain small species. However, we are increasingly finding that females may store sperm in sperm receptacula, which may be segmentally arranged at or near the anterior end. Sperm morphology has been related to the modes of fertilization. The round-headed sperm with a short acrosome and a long tail has been considered primitive since it is present in taxa that spawn into the water column. When fertilization takes place elsewhere, the sperm usually has another structure, often with greatly elongated heads and short tails.

In taxa with both feeding and nonfeeding (or brooded) larvae, eggs are much larger in the taxa in which the larvae do not feed. Nonfeeding larvae are present in all major groups of polychaetes and in some families they are the only kind of larvae present. The shift between feeding and nonfeeding larvae must have evolved more than once; the direction in which this shift has taken place cannot be considered settled in many cases.

Early development may take place in open water, in deposited egg masses, in brood chambers of various sorts, or internally, in the body of the females. After the early cleavages, which follow a pattern called spiral cleavage, as in many related phyla, and gastrulation, a trochophore larva develops. The trochophore consists of any upper episphere with a sensory tuft of cilia on the top and often a pair of small eyes. The episphere is separated from the hyposphere by an encircling prototroch, a ciliary band that in the polychaetes may consist of anything from a single row of ciliated cells to a broad densely ciliated girdle. The mouth is located on the ventral side, immediately posterior to the prototroch and is

often associated with a longitudinal midventral ciliary band, the gastrotroch. At the posterior end of the larva, a third ciliary band, the telotroch, is often also present. In feeding larvae the gut is fully developed and a pair of larval nephridia is present. When metamorphosis starts, segmentation starts posteriorly, just in front of the telotroch, internally the segments are first visible as paired mesoderm blocks on either side of the gut. These blocks eventually become hollow and the mesoderm forms the peritoneal lining and muscles and most other structures in the developing segment. The space inside each block becomes the secondary body cavity, the celom, which eventually contacts the exterior through nephridial ducts. Metamorphosis in most polychaetes is a gradual process of adding more segments with a progressive reduction in the prototroch and other larval structures; the body proportions of a newly settled juvenile may reflect what the adult worm will eventually look like, but in many cases considerable change in relative proportions of various body regions takes place during the later development. The body of the polychaetes may appear to consist of a series of repeated units, but as we become more familiar with postmetamorphic development it is becoming increasingly obvious that the polychaetes maintain integrated bodies with distinct proportionality between different regions.

The clitellates are hermaphroditic and, especially the terrestrial ones, have developed complex mechanisms to ensure fertilization and protection of the fertilized eggs. The clitellum, the excretory girdle will during the copulation secrete a cocoon in which the larvae develop. Clitellate development is always without a trochophore as described above for the polychaetes. Both the echiurans and the sipunculans have a trochophore. In the echiurans, metamorphosis follows a relatively brief trochophore stage. One unusual feature of the bonellid echiurans is that the larvae have indeterminate sex. If the metamorphosing larva settles directly on the substrate, it will become female; however, if the larva settles on the elongated prostomium of a female, it will become a dwarf male and live permanently connected to the female, essentially becoming a ready source of sperm when the female spawns.

The sipunculans follow the first trochophore with a prolonged larval stage in which they may stay in the plankton for several months. If an early trochophore happens to hit the substrate prematurely, it will not metamorphose, but will most likely die.

Systematics, Diversity, and Phylogeny

The phylum Annelida has recently undergone a massive restructuring as indicated above. The following outline of these changes follows some of the major changes, but all issues are yet to be resolved.

Traditionally the polychaetes were separated into errants and sedentaries (two equivalent groups in terms of numbers of species), since the 1950s this system has been replaced by one in which the group is separated into many orders, but without a clearly stated phylogenetic scheme to support the groups (see [Fauchald 1977](#) for an example). The classification presented here was proposed by [Rouse and Fauchald \(1997\)](#)

(Figure 6); it will certainly be improved when more information becomes available. Especially important will be a clearly recognized linkage between the clitellates and the polychaetes. In particular, the group called Scolecida in Rouse

and Fauchald turned out to be unsatisfactory when genetic information became available.

In addition to the approximately 80 families traditionally included among the polychaetes, a major change was

Figure 6 Diagram showing the current systematic subdivision of the Polychaeta. Only 54 of the 80 families have been included; most of the remaining families can be readily associated with the taxa where they fit but are sufficiently poorly known or lack so many features that including them would have distorted the current analysis. Eventually, we expect to be able to incorporate all families. Modified from Rouse GW and Fauchald K (1997) Cladistics and polychaetes. *Zoologica Scripta* 26(2): 139–204.

proposed by Rouse and Fauchald. The pogonophorans (including the vestimentiferans) have been considered a separate phylum (phyla). Their major features match the polychaetes well, and they are included here as single family polychaetes, Siboglinidae. Some of the unusual features, such as the “absence” of a gut are incorrect; the siboglinids have most tissues associated with the gut, but in the adults the gut is closed both anteriorly and posteriorly and the gut lumen is obliterated. Evidence from molecular systematics furnishes good criteria for including the siboglinids among the polychaetes, even if the exact placement among the canalipalpates is still uncertain.

Rouse and Fauchald included the myzostomids among the polychaetes; this group has been considered distinct for more than 100 years, and recently it has been shown that the apparent similarity to the polychaetes is incidental (see especially papers by Eeckhaut and collaborators). The myzostomids are associated with echinoderms and have a fossil record stretching back to the Paleozoic, so they certainly have a long separate evolutionary history. Recent molecular studies link the myzostomes to the annelids again.

The fossil record of the polychaetes is, not surprisingly, uneven, considering that they are soft bodied with very few, readily fossilizable structures. They were present in the middle Cambrian (in the Burgess Shale) in taxa resembling in certain respects, both recent canalipalpates and aciculates. In the same material is also found *Wiwaxia*, which may or may not have been a polychaete, but which appears to share certain details with members of a recent aciculate polychaete family, Chrysopetalidae. Jaws of various polychaetes have been reported present from the Ordovician on, these jaws were originally considered a separate group, Scolecodonta, but are now considered disarticulated jaws of aciculate polychaetes, especially the euniceans, which are still common in all kinds of environments. Whole body fossils have also been reported from other Paleozoic strata, and the presence of recent families has been suggested. Many of the whole-body fossils lack the diagnostic characters of recent taxa so the presence is often difficult to document. Calcified tubes similar to those present among the serpulids are present from early Paleozoic strata on, some of these tubes may have belonged to nonannelid taxa, but certainly some of them were serpulids. The upshot of the scattered records shows that most major taxa of polychaetes must have been present by the Ordovician and some clades may be even older than that. This suggests that each group has a long separate evolutionary history. Most of the groups were thus present before Pangaea was formed, which agrees with the very wide dispersal of all major polychaete taxa: they have been rafting on the continents. However, there is much evidence to show that individual species are capable of very rapid dispersal as invasive species, probably mostly through transportation of adults.

Polychaetes are important components of the bottom fauna at all depths of the oceans from beach sands to the soft mud of the deep-sea trenches. Recently a rich fauna of very unusual polychaetes has been found in both hot vents and cold seeps. Various polychaetes are also present in the pelagic environment throughout their life, more commonly the polychaetes have benthic adults but are present in the plankton for larvae for a varying period of time. In certain areas the polychaetes may make up as much as 90% of the standing

crop of benthic macrofauna, so any account of life in and on the sea bottom must take into account the activities of these worms.

Polychaetes often appear to be very widely dispersed geographically, and some species are considered cosmopolitan. Careful studies have in many cases shown that the records on which these distribution maps were based are erroneous. More than one species have been called by the same name: later investigators have shown that what was originally thought to be a single taxon often represented several distinct taxa. This correction of geographical records is important for our understanding of the biodiversity of many areas, and is in part the result of increased quality of analysis based on the development of statistical techniques and the emergence of molecular systematics or has been demonstrated in experimental studies. Many polychaetes are genuinely widely dispersed however, possibly because they can be transported on ship bottoms and in ballast water. Other forms of accidental introductions also have been demonstrated. Importation of a species of abalone from South Africa to California for use in aquaculture brought along small sabellid polychaetes that burrow into the shell of the South African abalone; the sabellid escaped and is now doing damage to native abalones not only in aquaculture but also in the wild. Other polychaetes, especially members of the family Spionidae, have been transported with importation of oysters, they burrow into the shells of oysters, forming mud blisters, which may have serious consequences for the oyster industry in certain areas.

Polychaetes may move around at the surface of the substrate on which they live, but even the most active species are usually cryptic, nestling in cracks and crevices, under the cover of sea weed or debris or along the edge of rocks where these meet sand or mud. Many polychaetes from a variety of higher taxa form tubes or burrows in which they live more or less permanently. Some, such as the onuphid *Hyalinoecia*, are capable of moving their quill-like tubes along, but others, such as the related *Diopatra* are sessile; in this genus the tube consists of a gray matrix which, where it reaches above the substrate, is decorated with shell fragments, wood or sea grass debris, and sea weed. The sabellids, especially the larger species, form tough, but pliable tubes, but the closely related serpulids have their tubes impregnated with calcium carbonate. Some species, such as certain glycerids, live in complex galleries with several openings on the surface; the worms move around in the galleries so that they can intercept small prey organisms moving around on the surface of the mud or sand.

The presence of polychaete tubes creates a microenvironment in many areas so that the sheer presence of these worms modifies sedimentation patterns and influences the relationship between the surface of the sediment and the overlying water.

In general, polychaetes feed on anything organic. Some taxa are obligate carnivores, but most species will feed basically on any kind of plant and animal fragments present, alive or dead. Several species take food particles out of the water column, mostly by creating small back eddies in flowing water so that particles in transport in the water will drop out of the flow. Only the chaetopterids truly filter the water for contained food and are specialists of that mode of feeding.

The nereidid polychaetes have been shown to be capable of filtering as well, but they are not morphologically structured for this activity. This may be true for several other polychaetes that are capable of building temporary tubes and driving water through the tube with undulatory motions. Incomplete mucus plugs will fetch particles in the stream. Many polychaetes feed by capturing small, light-weight particles in mucus strands and transporting them to the mouth along the palps, feeding mainly on the light fraction of particles in bottom load transport at the water–sediment interface, often creating or taking advantage of irregularities in the bottom. Some polychaetes feed at depth at the bottom of their tubes (malanids) and are thus capable of turning over sediments. The arenicolids are especially well known for their feeding in the intertidal sands and mud flats, these worms are large and as a consequence have considerable effect on the life conditions for all other inhabitants in the bottom. They are buried sufficiently deeply to avoid being the prey of plovers and other birds.

Certain polychaetes, such as the capitellids, include some of the most pollution-resistant species in the sea, capable of surviving in inner harbor waters where the organic pollution load is very heavy. Other polychaetes, such as some glycerids are extremely sensitive to change in sediment composition and oxygen levels in the water. This range of reactions to disturbance has made polychaetes much used in environmental research. Most of the taxa used have short generation spans and at most a very short larval life, making them ideal subjects for laboratory studies of heavy metal ions toxicity. Most of the species used in this kind of research can be maintained under very simple conditions and have contributed to giving polychaetes a reputation for being generally pollution resistant, but it is likely that this is a sampling error. The species used in research easily go into culture. The more sensitive taxa are much more difficult to keep in culture, but may be more generally characteristic of the group as a whole in terms of physiological requirements.

The clitellates include three ecologically very different groups: the small, fresh-water and marine microdriles; the large, terrestrial earthworms, and the leeches. The microdriles are at least partially very widely dispersed geographically, but thanks to increased study, characteristic faunal elements are becoming better documented. The earthworms include several species that have been transported by humans in soil. Many of them are invasive and move into new environment easily.

The leeches are interesting in that they are essentially carnivores, or parasitic on animals, but phylogenetical they are derived from groups that appear to have been feeding basically on detrital particles. The leeches are present in all three major environments, marine, freshwater, and terrestrial. The terrestrial leeches are linked to high-humidity environments. The best known leeches include the bloodsucking leeches, *Hirudo medicinalis*, which were used in bloodletting for curative

purposes in Western medicine. Some leeches are still used in surgery in helping with removing blood clots and other material at or near an incision. The leeches that have been sold as medicinal leeches turn out to belong to more than one taxon; but apparently the curative role is independent of species.

Echiurans are present in soft sandy and muddy marine environments where they can build up very dense populations. The best known echiuran is perhaps *Urechis caupo* (the fat innkeeper) from the US west coast. This is a very large, sac-like echiuran living in burrows in which it hosts a whole fauna of associated animals, most of whom live by stealing the food-nets produced by their host.

The sipunculans are present in most marine environments, they usually live in burrows from which they can evert their anterior end with the feeding tentacles and essentially brush up food particles from the surrounding of their burrows. They are often found in empty snail shells, in cracks and crevices in rocks and corals and even in the mangrove root mats in tropical environments. Because of their extended larval life, many species have been reported to be widely dispersed, but exact documentation of the relationships among the populations is often missing.

Glossary

Anhydrobiosis State of dormancy in various invertebrates due to low humidity or desiccation.

Cuticle Noncellular external layer of the body wall of various invertebrates.

Gubernaculum Sclerotized trough-shaped structure of the dorsal wall of the spicular pouch, near the distal portion of the spicules; functions for reinforcement of the dorsal wall.

Hypodermis Cellular, subcuticular layer that secretes the cuticle of annelids, nematodes, arthropods (see epidermis), and various other invertebrates.

Pseudocoelom Body cavity not lined with a mesodermal epithelium.

Spicule Bladelike, sclerotized male copulatory organs, usually paired, located immediately dorsal to the cloaca.

Stichosome Longitudinal series of cells (stichocytes) that form the posterior esophageal glands in *Trichuris*.

Stoma Mouth or buccal cavity, from the oral opening and usually includes the anterior end of the esophagus (pharynx).

Synlophe In numerous Trichostrongylidae, an enlarged longitudinal or oblique cuticular ridge on the body surface that serves to hold the nematodes in place on the gut wall.

Vermiform Worm shaped with tapering form both posteriorly and anteriorly.

What is a Nematode? Diversity in Morphology

General Characteristics and Synapomorphies

Despite numerous assertions that appear in the literature stating that nematodes are morphologically conservative, the contrary is actually true: Species of the phylum Nemata are extremely variable in their morphological characteristics. Because of this diversity, almost any broad statement regarding their anatomy probably should be tempered or qualified. Nevertheless, in general, nematodes are nonsegmented worms that generally lack external appendages. Most are vermiform, with tapering anterior (**Figure 1(a)**) and posterior ends (**Figure 1(b)**), cylindrical in cross section, and covered with a usually translucent (**Figure 1(c)**), flexible acellular cuticle secreted by an underlying cellular hypodermis. The cuticle may be smooth (**Figure 2**) or ornamented with rings (**Figure 3(a–c)**), longitudinal striations, spines (**Figure 3(b)**), or spikes or it may have well-developed wing-like structures called lateral alae very commonly on the externo-lateral surfaces (**Figure 4**). Some marine species have long setae (genus *Draconema* **Figures 5(a), (b), and 6**), which are modified sensory papillae that are probably used in movement and in detecting their environment. In contrast to all other nematodes some marine species have eye-spots that enable them to detect light in their environment (e.g., genus *Thoracostoma* **Figure 7**).

The fine-structure of the external body-cuticle is complex, acting to protect the animal from the external environment allowing it to remain homeostatic inside. The cuticle can be extremely resistant, and depending on the nematode species and its life-history attributes, for example, the cuticle of the nematode may be able to resist digestion in the most inhospitable stomachs in the vertebrate world. Whereas, nematodes may be extremely delicate, able to exist intact only within the osmotically balanced tissues of other animals (e.g., members of the Order (O) Filaroidea) and if moved from the isosmotic solution to one with fewer salts, they may explode and die in a most amazing display.

Nematodes are called “pseudocelomates” because in most forms, their celom is not completely lined with mesodermally derived cells and they are triploblastic. Possessing no circular body muscles, movement is accomplished by contraction and relaxation of longitudinal muscles in apposition to a hydrostatic skeleton. The body wall, is flexible and very strong. All nematodes maintain their form because their body fluids (in the hydrocoel) are under a positive pressure, relative to their environment, analogous to the way a water balloon maintains its shape. The cross-section in **Figure 8** shows *Vexillata* (a nematode that occurs in rodents of the superfamily Geomyoidea, and recently discovered in other rodents) the round shape of the body under the cuticle supports spines or aretes (the whole structure being called the synlophe). Nematodes have a complete digestive system with an anterior stoma just behind the mouth and usually a tri-radiate or triple muscle-pumping type of esophagus (**Figure 1(a)** and **(c)**) that can be muscular or glandular in structure (or both as occurs in certain species of the Filaroidea). The intestine, tubular in form, (**Figure 1(c)**) is usually a single cell in thickness and is lined on the peritoneal side with a thin collagenlike material and, internally, the cells are lined with microvilli to increase the absorptive surface area of the tubular intestine (Grassé, 1965; Maggenti, 1981; 1991a). The tubular intestine extends from the posterior of the esophagus straight to the anus or cloaca, sometimes showing outpouched cecae (blind sacs) or diverticulae near the esophageal–intestinal junction **Figure 9**.

Most nematodes are sexually dimorphic with separate sexes (diecious or amphigonous) and oviparous; however, some are ovoviparous and some are viviparous. Males usually have a cuticularized spicule or pair of spicules that are used to assist in the transfer of sperm to the females. Many species also have a gubernaculum (seen extended from the cloaca of a species of *Anisuraptodera* in **Figure 23**) that guides the spicule during copulation and also eversion of the spicules. Some species are hermaphroditic and in these cases the nematode produces both sperm and ova from the ovotestis of the same

Figure 1 (a) Anterior end of *Didelphoxyuris*, the pinworm of South American Marsupials, showing the small anterior stoma at the narrow end, followed by the well-developed muscular esophagus with a large posterior bulb. The esophagus is tripartite and serves as a muscular pumping organ, pumping food into the intestine. (b) Whole drawing of a predatory nematode of the genus *Mononchus* showing the general structures of a nematode including the tapering anterior and posterior ends and the ventral vulval opening just posterior to

Figure 2 Posterior end (tail) of a male *Paraspidodera* showing the relatively smooth cuticle, a sucker just anterior to the opening of the cloaca, and one spicule protruding from the cloaca.

individual at different times during ontogeny (Maggenti, 1991a; Malakhov, 1994).

A synapomorphy of the Nemata is the presence of non-contractile axonlike myoneural processes or extensions that run from the contractile or body portion of muscle cells to the neural junctions of the nerve cords.

Their width is usually less than 2 mm, even when extremely long. However even here there are exceptions, with the giant kidney worm, *Diectophyma renale* occurring in mustelids and canids sometimes attaining a size of greater than 15 mm by 1000 mm. The eggs of nematodes are also very similar in size with most ranging from 50–100 μm long by 20–50 μm wide with the exception being those of the antarctic marine nematode *Deontostoma timmerchioi* (40 mm in length of body) that has eggs that range from 870–1100 μm long by 240–350 μm wide (huge by nematode standards).

As mentioned above, nematodes are extremely diverse in size, shape, and structure. The following will only briefly touch on the expansive subject of nematode morphological diversity; for additional reading and exploration see the essential works and references therein of Maggenti (1981); and Grassé (1965 a and b).

External Covering – The Cuticle

An example of diversity in shape is that of the complex cuticular aretes found in species of the O. Strongylida: Trichostrongyloidea (parasitic in vertebrates) in which the exocuticle is modified into a series of cuticular aretes called the synlophe

midbody. The stoma is heavily cuticularized and bears a spike or spine that is used to puncture the cuticle of the prey. (c) Confocal microscopic image of the exophageal bulb and posterior part of the esophagus of a species of *Pratylenchus*. The cuticle can be seen as the outer light outline of the nematode with an underlying brighter layer showing the cellular hypodermis. The bulb shaped posterior part of the esophagus attaches via a valve to the single cell thick-tubular-intestine, shown here as an optical section just posterior to the esophageal bulb.

Figure 3 (a, b, c) Anterior ends of marine nematodes showing rings and spines on the cuticle. (c) Whole drawing of a marine nematode of the genus *Desmoscolex* showing heavily cuticularized rings and long setae.

Figure 12. In these forms, it is thought that the ridges running down the length of the body of the nematode are used in maintaining their position in the intestine of their hosts (**Figure 8**). Other forms have an exocuticle composed of serrated ridges (**Figures 3(a), (b), 10, and 11**), bumps, or may be very smooth (**Figure 2**). Some groups (Heterakoidea – parasitic commonly in birds and mammals) possess large cuticularized suckers just anterior to the cloaca that are surrounded by sensory papillae that evidently allow the male to find the female in the intestinal tract of the host as in *Paraspidodera* of rodents (**Figures 2 and 13**) and *Ansiroptodera* from rodents (**Figure 23**). Marine nematodes of the genus *Dracnema* (**Figures 5(a) and 6**) and *Desmoscolex* (3c) have a wildly modified cuticle relative to most nematodes and very large hair-like and segmented cuticular setae that the nematodes use for both movement and detecting its environment (**Figures 5(a) and 6**). One curious structure that occurs in all Nemata is the amphid, a highly variable sensory organ that can be very obvious as in *Desmodera* (**Figure 10**) or very inconspicuous as in *Chambersiella* (**Figure 18**).

The Alimentary Canal

The mouth of the nematode (**Figure 14(a)**) provides the anterior opening to the external environment, which connects to the stoma leading posteriad to the muscular esophagus (**Figures 15–18**). The stoma may be quite reduced or absent as in the case of members of the Trichostrongyloidea (O. Strongylida) or they may be well developed such as that found in *Clarkus* (**Figure 16**) and *Mononchus* (**Figure 1(b)**) and capable of inflicting damage on prey items or it may be modified into horny toothlike structures that are used to attach to the intestinal villi of the host animal (e.g., *Ancylostoma*

Figure 4 Lateral alae of *Aspidodera*, a parasite of South American xenarthrans, marsupials, and rodents. The ala or wing runs the length of the body possibly providing support for the nematode in the gut of its host. The cellular hypodermis of the nematode can be seen just inside the translucent cuticular layer.

Figure 19). In mammalian gut parasites of the genus *Trichuris* (Adenophorea: Trichuridae) the stoma is lacking and the esophagus is formed of stichocytes comprising a stichosome, which is glandular in function, but many other plant-parasites such as the Adenophorean ectoparasitic, below ground root-feeders (capable of transmitting viruses between and among plants *Xiphinema*, *Longidorus*, or *Dorylaimus*: O. Dorylamida: Longidoridae) have a tubular stoma with the posterior parts of the stoma modified into a spear that is used to penetrate plant

Figure 5 (a, b) The expanded head with visible cuticularized stoma of a species of *Draconema*, a marine nematode. Long setae that are probably used to move and to sense the environment are visible in this photograph. (b) Scanning electron micrograph of the anterior end of a marine nematode showing the long setae and a well-developed amphid just ventral and posterior to the lip rings.

Figure 6 A whole drawing of a male of *Draconema* sp. illustrating the large setae, spicules, testis, and large expanded stoma and head.

Figure 7 Cuticularized "eye-spots" in the marine nematode *Thoracostoma*. Located at about the mid-part of the esophagus, this nematode can detect light in its environment.

Figure 8 Cross section at midbody of *Vexillata armandae*, a species of nematode parasitic in rodents of the genus *Perognathus* in New Mexico, USA. This photograph shows the spines (aretes) in the cuticle, called the synlophe in Trichostrongyloidea. Inside is the hypodermis lining the body of the nematode. The reproductive tract and the intestine are not visible in this photograph.

Figure 9 Anterior end of a species of *Criconemoides*, an external root feeding plant parasite. The rings of the cuticle can be seen from the head end posteriad, and the strong cuticularized stomatal spear is clearly visible in this photograph.

Figure 10 Anterior end of a marine nematode of the genus *Desmodera* showing the rings of the cuticle and a well-developed circular amphid.

cell-walls as in *Dorylaimus stagnalis* (Figure 20). The Secernentean plant endoparasitic nematode of the genus *Pratylenchus* (Figure 21(a)) also has a modified stomatal spear (much more delicate than those found in *Dorylaimus* sp.) with which it penetrates plant cells as the nematode moves through the tissues and cells of the plant (usually below ground).

The Reproductive System

The reproductive system of most animal parasitic nematodes is adapted to produce extremely large numbers of eggs (e.g., *Ascaris*). Some characteristics of larger animal parasitic nematodes include very large body, two large ovaries, and an equally large uterus. Free-living nematodes generally have much smaller bodies, and are therefore individually less prolific. However, the reproductive systems of most nematodes have the following basic structural similarities: Most

Figure 11 Scanning electron micrograph of the posterior end of a male marine nematode showing rings of the cuticle and small papillae lateral to the cloaca.

Figure 12 Scanning electron micrograph showing the posterior end of a species of *Paraspidodera* (a parasite of the cecum of rodents of the genus *Ctenomys* in Bolivia) with a spicule everted.

females have two ovaries, one anterior (as in *Pratylenchus* Figure 21(b)) and one posterior, each connected to an oviduct and uterus with the uteri connecting to the vagina, terminating in the vulva. Males usually have one testes as in the Secernentea or two as in the Adenophorea, a seminal vesicle and a vas deferens (Maggenti, 1991a) connecting to the outside via the cloaca (Figure 13), which is a joining of the reproductive system and the rectum. Secondary sexual organs in male nematodes are usually much more pronounced and variable than that of the female (Figures 2, 6, 11, 12, 13, 22, 23, 24, and 25) and most males have one or two spicules (Figure 22), a spicular pouch, sometimes with a spicular sheath (Figure 24), and a gubernaculum. (Figure 23). Some males of the O. Strongylida have a well-developed copulatory bursa (Figure 22).

Figure 13 Close up scanning electron micrograph of the sucker and cloacal opening of a species of *Paraspidodera* (a parasite of the cecum of rodents of the genus *Ctenomys* in Bolivia). Numerous sensory papillae can be seen on the cuticle around the cloaca.

Some plant-parasitic nemas produce eggs directly into the plant where the nematode lives (in the case of species of the genus *Pratylenchus*, the female produces eggs that hatch within the tissues of the plant and the juveniles begin feeding), whereas in others such as *Heterodera* (which are ectoparasites) the body of the female fills with eggs, forming a sac that eventually dries and transforms into a resistant cyst with the juveniles within capable of resisting environmental extremes.

The Ubiquitous Nature of Nematodes

There are few habitats on earth unoccupied by nematodes. Over a century of both biological surveys and informal collecting has led many biologists to believe that the Phylum Nemata is probably the most ubiquitous of all animal groups. Early in the history of scientifically based biological investigations, pioneers of microscopy opened a new window into the previously unseen microscopic world of the soils.

Descriptions of the “invisible” life seen by pioneers of microscopy such as Antony van Leeuwenhoek evoked images of a wonderfully diverse and dynamic community of worms and other organisms. Subsequent investigations by other early researchers began to open up the unseen world of the nematodes.

Early Views of Nematode Diversity – The Human Perspective

Humans have been parasitized by nematodes from the earliest times. Eggs of the pinworm *Enterobius vermicularis* and the whipworm *Trichuris trichuria* occur in coprolites dated to about 7000 years old (y.o.) from dry areas of Peru and eggs of the hookworm *Ancylostoma duodenale* have been reported from coprolites dated to around 7230 y.o. in eastern Brazil (Arujo *et al.*, 2008). *Ascaris lumbricoides* has been positively identified from human coprolites dated to about 28,000 y.o. from caves in France, but this is the only occurrence of a record this old. The seeming dearth of other nematodes from human remains older than about 7000 years appears to be due to the fact that

Figure 14 (a) Anterior end of a species of *Paraspidodera* (a parasite of the cecum of rodents of the genus *Ctenomys* in Bolivia) showing three huge lips, the stomatal opening in the middle of the lips and large anteriorly directed sensory papillae on lips 2 and 3 near the outer part of the photograph. (b) Head-on-view of a predaceous nematode as might be seen from the perspective of a mild mannered bacterial feeding form such as *Caenorhabditis* just before it is devoured.

organic material comprising the coprolites themselves do not preserve well enough to last that long (Karl J. Reinhard, personal communication).

In what is thought to be the oldest surviving written account of *Ascaris* in humans (dated to approximately 4700 y.o. (in China)), foods to avoid and a description of the symptoms of humans infected with these worms were accurately given (Maggenti, 1981). In the area of the Nile River Valley, early Egyptian physicians recorded the presence of both *Ascaris* and *Dracunculus* (the “Guinea Worm”) in an ancient papyrus manuscript (written by Egyptian physicians around 3552–3550 y.o.) which was obtained and translated by the Egyptologist “Ebers” in 1872 (Chitwood and Chitwood 1977; Maggenti, 1981). In the extant literature, the first mention of a nematode from a nonhuman animal was by Hippocrates

Figure 24 Posterior end of *Trichuris* from a Bolivian species of *Ctenomys*. The long spicule and everted spicular sheath can be seen.

about 2430 years ago where he described the occurrences of pinworm nematodes of both horses and human females. From that time, little further was discovered until Albertus Magnus and Demetrios Pepagomenos (in the thirteenth century, Rausch, 1983) recorded nematodes from falcons (also see Chitwood and Chitwood, 1977).

With the development of the microscope and the emergence of Europe from the dark-ages, knowledge of nematodes as parasites of plants and animals and of free-living forms expanded rapidly. It was found that nematodes occurred everywhere people looked, in fact, Anton van Leeuwenhoek first recording the presence of vinegar eels "*Anguillula aceti*" in his vinegar stored for personal use in a letter dated 21 April 1676 although he was not aware that others had reported finding nematodes some time earlier (Dobel, 1932).

Recent estimates of infections of humans with common human parasitic nematodes give the following numbers

(Crompton, 1999): Of a total human population size of about 6 billion individuals (in the year 2000) the strongylid hookworms, *Ancylostoma duodenale* and *Necator americanus* infect about 1,298,000,000 (22%) and the large intestinal nematode, *Ascaris lumbricoides* occurs in about 1,472,000,000 (25%) people at any one time in the world. Obviously, many people harbor more than one species of nematode at a time, and it is common for people to sport *Ascaris*, *Necator*, *Trichuris*, and *Enterobius* simultaneously. The author provides the following estimate to indicate just how important these organisms are in the web of life on earth. To put the number of infections of just humans in perspective, the author made the following extrapolations: An adult female *Ascaris* produces 200,000 eggs per day at an average rate of about 5grams of eggs per year. Actual data for *Ascaris* in humans that are infected show an average of 18 worms per infected person. Given that $\frac{1}{2}$ of these are females, the author calculated that nine worms per person will produce about 45 grams of eggs in the feces of the host per year. In one year the total population of *Ascaris* in humans worldwide is

Figure 25 Posterior end of the filaroid nematode *Litomosoides* from *Ctenomys opimus* from high-altitude western Bolivia. Note the dimorphic nature of the spicules in this species one being long and filamentous the other being short and stubby.

conservatively estimated to produce 66,240,000 kg or 66,240 metric tons (72,864 tons (English)) of eggs; this is equal in weight to about 348 large adult blue whales, 8,832 adult male elephants, or 364 fully loaded railroad coal cars.

Estimates of the number of human infections in the year 2000 by other species of parasitic nematodes are shown in **Table 1**. At the present time, approximately 138 species of nematodes have been reported from humans (Crompton, 1999) with 32–36 being host specific.

The Science of Nematode Diversity

Nathan A. Cobb, one of the first scientists in North America to advance nematology, was a student of the renowned German zoologist, Ernst Haeckel. After just a few years of research spanning the globe from Europe, Australia, and North America, Cobb amassed a huge amount of knowledge and came to have a deep appreciation of the immense number of species that existed. With scientific knowledge based on keen observational skills, he understood the nature of both the great numerical density and species diversity of nematodes in all habitats of the globe that he examined. Thus armed, he wrote the following:

"In short, if all the matter in the universe except the nematodes were swept away, our world would still be dimly recognizable, and if, as disembodied spirits, we could then investigate it, we should find its mountains, hills, vales, rivers, lakes, and oceans represented by a film of nematodes. The location of towns would be decipherable, because for every massing of human beings there would be a corresponding massing of certain nematodes. Trees would still stand in ghostly rows representing our streets and highways. The location of the various plants and animals would still be decipherable, and, had we sufficient knowledge, in many cases even their species could be determined by an examination of their erstwhile nematode parasites.

We must therefore conceive of nematodes and their eggs as almost omnipresent, as being carried by the wind and by flying birds and running animals; as floating from place to place in nearly all the waters of the earth; and as shipped from point to point throughout the civilized world in vehicles of traffic." (From Cobb (1914).

As if challenged by this assertion, scientists have tested Cobb's hypotheses by examining the extremes of the biosphere on earth to evaluate the limits of nematode life. Through these investigations, biologists have now shown that nematodes are living and reproducing everywhere on Earth
